The different diagnostic appearances of scutella on the backs of the gray mouse are as follows:

<i>Favus griseus.</i>	<i>Favus sulfuricus tardus.</i>	<i>Favus sulfuricus celerior.</i>
Scutella of medium size (lentil); thick; on upper surface flat or raised, not saucer-shaped; gray-yellow, like old wash leather, without shine and smooth; pierced all over by fine hair and spurs of hairs.	Scutellum becomes very large and covers the entire back; is thick; on upper surface hollowed out into cup shape; surface covered with small studs, folded, yellow-white or cream-colored; of leather-like smoothness, in places shining; hairs are pressed down; do not pierce the crust.	Scutellum remains small, about size of pepper-corn; on upper surface cup-shaped, smooth, but without shine; around the periphery light-ochre color, toward the center more whitish, on the curled-up edge horny-like brown; pushes the small hairs back, while the spurs of hairs pierce through.

These three forms of favus, when inoculated on mice, will give their characteristic scutella, and two of them have been found spontaneously on captured mice.

**A Case of Malignant Disease of the Stomach in which Gastro-enterostomy was considered.**—At a meeting of the Philadelphia County Medical Society, held on February 10th, Dr. John B. Roberts read the following paper:

I desire to briefly report the result of a case in which I was only deterred from making preparation for gastro-enterostomy by the debilitated condition of the patient, but in which the post-mortem findings showed the inutility of such an operation. The delay which prevented me from subjecting the patient to the expense and anxiety of so serious an abdominal operation is so justified by the pathological conditions that it has caused me to present the specimen for examination.

Upon being summoned to another State for surgical consultation, I found a man about fifty-two years of age suffering from great pain in the epigastrium. He was vomiting large amounts of fluid. The temperature was normal, but the muscular weakness was great, and sleeplessness pronounced. The abdomen was distended with gas, and there was a marked prominence in the neighborhood of the left hypogastrium. The patient had suffered for about four years with dyspeptic symptoms, during which time he had been under the care of many physicians. He had recently been treated by lavage, which relieved the pain temporarily, and he had suffered with such obstinate constipation as made the attending physician think that there was some obstruction in the alimentary tract. It was this as well as the excessive pain that induced him to call in surgical aid.

The character of the vomiting, the situation of the prominence in the left hypogastrium, and the general aspect of the case made it very evident to me that it was one of dilatation of the stomach. I gave an opinion that it was very possible that there was malignant disease in the neighborhood of the pylorus; but it was impossible to determine the question because of the distended abdomen, and the diagnosis was hence left undecided. The administration of food by the mouth was stopped entirely, and enemata of peptonized milk combined with whisky were given every two hours night and day. Lavage was continued to empty the stomach and relieve pain. This line of treatment was continued for about three weeks. The patient's discomfort was relieved, the pain disappeared, the vomiting discontinued, and the consequent reduction of tympany rendered it possible to detect a hard mass below the liver in the median line. The bowels in the mean time had become regular by the occasional administration of cascara. This for two weeks, however, was not needed, because of spontaneous evacuation of the bowels, probably due to the enemata. Microscopic examination of the vomited matter showed me that blood was present in the ejecta, and I now made a diagnosis of malignant disease.

At the end of three weeks small amounts of nourishment were given by the stomach. We commenced with a drachm of peptonized milk with a few drops of whisky every two hours, and daily diminished the amount of food administered by the rectum. Gradually the amount of food taken into the stomach was increased until it reached three ounces every two hours. The prolonged rest during the period above mentioned seemed to have been beneficial to the stomach, so that the small amounts of food given at frequent intervals were digested without pain; there was no vomiting, though the tympany became more or less prominent.

At the time he began to take food by the mouth I told the patient that he had malignant disease of the stomach, and that exploratory examination was proper with a view of determining whether an artificial opening could be made between the stomach and intestine, or the growth removed. This was deferred until the strength of the patient should be somewhat improved under gastric alimentation. The patient, however, continued to lose ground, and died about a month after my first visit. When the food given by the stomach reached three ounces and a half he began to have pain.

The autopsy showed, as the specimen makes clear, malignant disease infiltrating about one fourth of the long diameter of the stomach

with several nodular masses at the pylorus. The pylorus, however, is sufficiently patulous to admit readily the introduction of a finger-tip. There was, therefore, no marked obstruction. The cardia is much thinned, while the middle portion of the stomach presents the normal thickness and characteristics. An adhesion has taken place between the stomach and the liver at the point where the growth is most marked.

Gastric dilatation had occurred secondarily to malignant disease of the pylorus. The only time at which it seems to me gastro-enterostomy would have been wise was previous to his coming under the care of Dr. H. A. Stout, who called upon me for assistance; and it is very doubtful if at any time the operation would have been beneficial. The pylorus, as shown at the autopsy, must have had an opening as large as would probably have been made had the operation in question been performed; and the infiltration of the wall of the stomach for one third of its length would have made the area for an opening between the stomach and intestine limited. An opening would have had to be made between the thinned and dilated portion of the stomach at the cardiac extremity and the large area infiltrated with malignant growth toward the pyloric end. This, of course, could have been done, but prolongation of life would probably not have been gained.

The facts that the man was walking about and attending to business and that the tumor presented no external manifestations make it extremely probable that an operation would not have been suggested previously to the time he came under the care of the physician who consulted me, except by an enthusiast.

I present the case partly because of the interesting character of the specimen, and partly as a contribution to a branch of abdominal surgery which is assuming increased importance.

The recent series of cases reported by Dr. N. Senn have been read by me with great interest; but the conclusion has almost been forced upon me that many of them were cases that scarcely justified operative procedure. Perhaps I am too conservative; but may it not be that he is too enthusiastic?

**The United States Marine-Hospital Service.**—The surgeon-general, Dr. Walter Wyman, has issued the following notice, dated February 23, 1892: A board of officers will be convened in Washington on May 2, 1892, for the purpose of examining applicants for admission to the grade of assistant surgeon in the U. S. Marine-Hospital Service. Candidates must be between twenty-one and thirty years of age and graduates of a respectable medical college, and must furnish testimonials from responsible persons as to character.

The following is the usual order of the examination: 1. Physical. 2. Written. 3. Oral. 4. Clinical. In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify for service in any climate. The examinations are chiefly in writing and begin with a short autobiography by the candidate. The remainder of the written exercise consists in examinations in the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and the natural sciences. The clinical examination is conducted at a hospital, and, when practicable, candidates are required to perform surgical operations on the cadaver.

Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur. Upon appointment, the young officers are, as a rule, first assigned to duty at one of the large marine hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco. After four years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority and after due examination as vacancies occur in that grade. Assistant surgeons receive sixteen hundred dollars, passed assistant surgeons eighteen hundred dollars, and surgeons twenty-five hundred dollars a year. When quarters are not provided, commutation at the rate of thirty, forty, or fifty dollars a month, according to grade, is allowed. All grades above that of assistant surgeon receive longevity pay, ten per centum in addition to the regular salary for every five years' service up to forty per centum after

twenty years' service. The tenure of office is permanent. Officers traveling under orders are allowed actual expenses. For further information or for invitation to appear before the board of examiners, address Walter Wyman, M. D., Supervising Surgeon-General, M.-H. S.

**The New York Academy of Medicine.**—The special order for the meeting of Thursday evening, the 3d inst., was the reading of a paper on Cases of Appendicitis illustrating Different Forms of the Disease, with Remarks, by Dr. Charles McBurney.

At the next meeting of the Section in Genito-urinary Surgery, on Thursday evening, the 10th inst., Dr. J. E. Kelly is to read a paper on The Anatomy of the Bladder, and the chairman, Dr. E. L. Keyes, will open a discussion of the question Pus in the Urine—how to discover its Source?

At the next meeting of the Section in Pædiatrics, on the same evening, there is to be a discussion on Empyema, by Dr. H. Koplik, Dr. J. W. Brannan, Dr. J. H. Ripley, and Dr. J. W. Roosevelt.

At the next meeting of the Section in General Surgery, on Monday evening, the 14th inst., a paper on Multiple Tendon and Nerve Suture with Perfect Recovery in Spite of Suppuration will be read by Dr. H. Lillenthal, and one on Fibrous Mammary Tumors by Dr. C. N. Dowd.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. Walter Wyman, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for February 26th :

CITIES.	Week ending—	Population, U. S. Census of 1890.	Total deaths from all causes.	DEATHS FROM—

**The Prophylaxis and Treatment of Influenza.**—In the February number of the *Satellite of the Annual of the Universal Medical Sciences* we find the following abstract of the teachings on these subjects in Dr. Cyrus Edson's book on *La Grippe and its Treatment*: Three indications are to be fulfilled: (1) Means must be taken to assist the system to rid itself of the poison to which the attack is due; (2) pain must be relieved; and (3), not the least important, depression must be counteracted. The first indication is obtained by means of castor oil or two compound rhubarb pills. Three or four three-grain powders of phenacetin are usually sufficient to relieve headache and muscular pains. Salol, two grains and a half to each dose, may be added to the phenacetin with advantage. He deprecates antipyrine and its congeners, which serve to augment the depression, and recommends instead Hoffman's anodyne, which is diaphoretic, diuretic, and stimulant. To overcome depression during and after the disease, he recommends the free use of tonics. He repeats Professor Laffont's (of Lille) recommendation of coca preparations, those of Mariani being given the preference. During the disease a hot grog, one third Mariani wine of coca and two thirds sweetened water, is administered, taken very hot, several times

a day, the slight diaphoresis induced being a valuable addition to the tonic action. (The editor, in the coming issue of the *Annual*, recommends the exhibition of coca in the early stages of the disease, with a view to counteract the impending asthenia and curtail the disease. Six grains of blue mass are first ordered, and, as soon as a couple of movements have been obtained, two tablespoonfuls of Mariani coca-wine are given every two hours; lozenges, each containing two grains of coca leaves and one twelfth of a grain of cocaine, contribute greatly to ward off the pharyngo-laryngeal complications. A six-per-cent. solution of cocaine, applied occasionally to the nasal mucous membrane, directing the cotton-covered probe toward the roof of the nose and anteriorly, reduces markedly the pain caused by involvement of the frontal sinus. He fully agrees with the author as regards the contra-indication of antipyrine.) Edson considers champagne, generous wines, tonic doses of quinine, iron, and strychnine also of value. The catarrhal irritation of the air passages is best allayed by inhalations of compound tincture of benzoin. Chloroform liniment is recommended as a rubefacient: opium and carbonate of ammonium for the cough. The treatment of pneumonic *grippe* is essentially the same as that of uncomplicated pneumonia, the author emphasizing the advisability of preserving the strength of the patients.

**To Contributors and Correspondents.**—The attention of all who purpose favoring us with communications is respectfully called to the following:

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Original Communications.

A REVIEW OF  
FIVE YEARS OF DERMATOLOGICAL PRACTICE  
IN NEW ORLEANS.\*

By HENRY WILLIAM BLANC, B. S., M. D.,

HEALTH OFFICER, UNIVERSITY OF THE SOUTH, SEWANEE, TENNESSEE;  
FORMERLY DERMATOLOGIST TO THE CHARITY HOSPITAL, NEW ORLEANS;  
LECTURER ON DISEASES OF THE SKIN, TULANE UNIVERSITY OF LOUISIANA;  
INSTRUCTOR IN SKIN DISEASES AND SYPHILIS, NEW ORLEANS POLYCLINIC;  
CHIEF SANITARY INSPECTOR FOR THE CITY OF NEW ORLEANS, ETC.

HAVING found it necessary to change my residence from Louisiana to the more bracing climate of Tennessee, it seems right and proper that I should give an account of my stewardship in the field that I have surrendered, and more especially so as no full statement has ever before been made, so far as I am aware, of any systematic dermatological work performed in the Gulf States.

Reports of skin diseases observed in the South have occasionally appeared in our journals, but the writers have only pointed out the presence rather than the prevalence of these affections in their section, and have failed to convey any idea of their relations to race and climate.

We are familiar with the class of diseases commonly observed in Chicago, New York, and Boston, but the dermatological practice of New Orleans and other large Southern cities has up to this time been an unknown quantity.

The writer took charge of and organized the department for skin diseases in the great Charity Hospital of New Orleans in October, 1885, and surrendered it in July, 1891, after a period of nearly five years, and was the first dermatologist ever appointed by the administrators of that institution.

This paper records cases observed during this period both at the hospital and in private practice, and of every one here referred to careful notes have been taken. A number of cases seen in public and private practice were not recorded, owing to a variety of causes, and of course they can not figure in these statistics.

With the exception of syphilis, the venereal diseases are all excluded, and also the eruptive fevers, including vaccinia, as these would be out of place in the present analysis. Otherwise the last-mentioned affections would occupy a conspicuous portion of this report, as the writer's position of chief sanitary inspector of the Louisiana State Board of Health has given him unusual opportunities for observing the eruptive fevers, while it also made him the head of the bureau of vaccination during his tenure of office.

The following table, representing some seventy-five varieties of skin disease, is arranged to show sex and color, but it must be admitted that the record of colored cases is quite incomplete, due to the fact that negroes are not treated in the same department of the hospital as the whites, thereby causing some confusion in the records. It may be safely said that one half of the cases of skin disease in negroes

who applied for treatment at the hospital are not recorded here at all:

*Acne*.—This disease constituted 5.33 per cent. of all the diseases treated. A large majority of the cases of acne were seen in private practice and among the better class of people. Acne is quite common among the lower orders, but for obvious reasons an affection that produces so little pain and inconvenience is not apt to be brought to a hospital for treatment until increasing disfigurement causes its possessor to look about for a remedy. Negroes are not so subject to acne as the whites, and when they have it it is usually of the papular variety, seldom becoming pustular, and is accompanied by a mild seborrhœa oleosa. Under this heading are included a number of cases of rosacea, associated almost invariably with some of the papules of acne. The remaining cases were varieties of acne vulgaris, with the exception of two cases of *acne atrophica*, to which I prefer applying the title of *acne rodens*, in order to avoid confusion with certain atrophic conditions sometimes noted in strumous persons following the resolution of the pustule of acne vulgaris, or common acne.

The clinical history of these cases of *acne rodens* will be reported elsewhere.

*Chloasma*.—Out of nineteen of these cases there were eighteen in females, and six were negroes. Most of them were women between twenty and forty years of age, and all of them had passed the age of puberty when the disease began. The majority had some disorder of the menstrual function, and several were, or had recently been, pregnant.

Two young women (unmarried) who had no evidences of menstrual disorder were exceedingly anæmic.

*Chloasma gestationis* is, perhaps, more common in Louisiana among negro women than among white women. The pathology of this disease being a displacement of pigment, we find that in brown and black negroes, and to a less extent in the mulattoes, the skin turns lighter, instead of darker as in the case of the whites. The intensity of the shade depends upon the natural color of the negro, being darker in darkest skins. The edges of chloasma patches in negroes are not so clear-cut and well-defined as in cases of albinism and vitiligo, and the light patches have more pigment in chloasma.

*Dermatitis*.—The class of eruptions usually placed under this heading are burns and scalds (d. ambustionis), inflammations due to injuries, such as excoriations, contusions, and the like (d. traumatica), and inflammations due to external irritants.

Seven cases were due to mosquito bites, four out of the seven being in persons who had just come to the city from a foreign country. Not using mosquito-bars, as is the custom in New Orleans in the summer season, they were devoured by these little pests, in several cases, from head to

foot. The scratching that ensued set up considerable inflammation, with the formation of pustules, and medical aid was sought. An interesting case was that of a young Russian who had acquired malarial fever in Costa Rica. On his way up the river to the city he was stung by mosquitoes from top to toe and then deposited in the hospital while delirious from fever. Arriving in my absence, the ambulance surgeon was much concerned as to how to dispose of a case which looked like an early stage of small-pox, and the patient's not speaking the language made the case all the more perplexing. When he was seen by me a little later, the diagnosis was made by noting the presence of minute hæmorrhagic puncta in the center of the pinkish papules, this being the point where the proboscis of the insect had been inserted. Under this heading are included forty-one cases of dermatitis venenata, thirty-five being in males and six in females. The cause of this eruption was usually ascertained to be the *Rhus toxicodendron*, though several cases were due to irritation from dyes.

*Dermatitis Herpetiformis*.—Of this affection, sometimes known as Duhring's disease because of the special study which this writer has given to it, there were four cases, all white, three being females. One of the cases is the *impetigo herpetiformis* of Hebra; but, as it evidently belongs to the group of cases described by Duhring, a brief recital of its clinical history is here appended:

E. L., aged twenty-nine years, native of Mississippi. Has five children, and when first seen had been pregnant five months and a half. History of having caught cold while carrying her fourth child, but had no eruption, only great itching of body during the week following its birth. With the fifth child an eruption appeared when quickening was felt, and lasted till her baby was three weeks old. She is now pregnant with her sixth child, the eruption having appeared one day before quickening was felt. The lesions appeared as circular, erythematous patches, well marked on the chest, back, and arms, but not clearly defined elsewhere, though occurring all over the body except the head. These patches were deeper in color at the periphery, giving them a ringed appearance. On the rings were vesicles, blebs, and pustules in all stages of development. They were not numerous, however, some rings having but three or four of these lesions. She stated that when the eruption first appeared the blebs were very numerous.

Patient's reason for applying for treatment was the incessant and intolerable itching, worse at night. This caused her to greatly aggravate the eruption, as she was unable to desist from scratching. Constant regulation of the diet and bowels and a carbolic salve (ʒ ss. to ʒ j) ameliorated, but did not cure, the itching. She was not seen after her child was born.

*Dysidrosis*.—Without pausing to give my reasons for separating this affection from *pompholyx*, a disease with which some writers have attempted to identify it, I will give briefly two cases of the disease classed under this heading:

CASE I.—Mr. A. B., aged fifty-six years, native and resident of New Orleans. Has been at times a hard drinker. Is suffering with a rodent ulcer on bridge of nose. Is corpulent, and has enlarged capillaries in skin of face, giving it a ruddy appearance.

On the bridge of the nose, on the temples near the eyes, and on the forehead here and there are little sago-grain appear-

ances, which are quite tense when pressed, but which emit when broken a watery liquid, acid in reaction. These do not itch and cause no inconvenience. It was noticed that some of them, after being incised with a small knife, remained dark for ten or fifteen days thereafter, on account of the venous blood that passed into them after the incision. They then healed and did not reappear, so far as I am aware.

CASE II.—MRS. M. E., aged forty-eight years, native of Germany. Has also ringworm of the thighs, which has spread on to the abdomen. General health good. Passed the climacteric period four years ago. Was formerly a wine-drinker, but has been taking a good deal of beer for the past two years. Is stout and plethoric, having dilated blood-vessels on the face.

Has noticed that during the past three summers a little sago-grain eruption would appear on her face and disappear in winter.

This eruption consists of vesicles of the size of a small pea, slightly raised above the skin, but also quite deep beneath the surface. They do not itch, and are located on the forehead, temples, nose, cheeks, and chin, being most numerous on the temples. After puncture, a hæmorrhage takes place in them, as in Case I. The liquid in them caused litmus paper to turn red. They all disappeared after incision.

Of the eight cases recorded, two were affected on the face alone, two on the hands alone, two on the toes alone, and two on hands and toes.

*Eczema.*—This affection, the commonest of all the diseases of the skin, has a fair share numerically among the diseases mentioned in this report, though it is not as common in New Orleans as it is in certain other localities. For example, the five hundred and twenty cases of eczema here reported are 25.7 per cent. of the total number of cases recorded in a period of five years. This is a lower percentage than that of the combined returns of the American Dermatological Association for the ten years between 1878 and 1887, for, out of 123,746 cases of skin disease recorded during that time, 37,661 cases were eczema, a percentage of 30.43.\*

In my cases, as in those referred to, the eruptions produced by the *Acarus scabiei* and the *Pediculus* are classed as *scabies* and *pediculosis*, and are enumerated elsewhere.

The following table illustrates the ages of patients suffering with eczema:

TABLE II.

*Ages of Patients with Eczema.*

Under one year.....	32
“ two years.....	14
“ three years.....	12
“ four years.....	7
“ five years.....	10
Between five and ten years.....	34
“ ten and fifteen.....	23
“ fifteen and twenty.....	43
“ twenty and thirty.....	86
“ thirty and forty.....	80
“ forty and fifty.....	75
“ fifty and sixty.....	57

\* In an analysis of 8,000 cases of skin disease Bulkley found 2,679 cases of eczema, or 33.48 per cent. See *Archives of Dermatology*, vol. viii, No. 4, October, 1882.

Between sixty and seventy.....	38
“ seventy and eighty.....	9
Total.....	520

There were seventy-five cases of eczema in children under five years of age, being 14.4 per cent. of the total number of cases treated. This percentage is small when we compare it with Bulkley's figures drawn from a larger number of cases.\* In 2,500 cases of eczema he reported 614 cases occurring under the age of five years, or 24 per cent.

Referring to Table I, it will be seen that 481 patients were white and 39 colored, while 301 were males and 219 females.

Table II shows that no age is exempt from this disease, and that the greatest number of cases occurring in a decade was in persons between the ages of twenty and thirty. There were seven between the ages of four and five, and nine between seventy and eighty. So youth and age may be alike affected.

*Epithelioma.*—A large majority of these cases were of the rodent ulcer, or superficial variety of epithelioma, and had not involved the neighboring glands. Eight cases were of the deep variety, and characterized by all the clinical and pathological symptoms noted in malignant disease. Some still presented the flat, waxy node so characteristic of this disease, while in others this had already broken down into crust-covered ulcers. The face is the common seat of these lesions, either on the cheeks, nose, temple, or forehead.

The youngest patient observed was a white man twenty-eight years old. The lesion occurred on either side of his nose as a waxy tubercle. After its removal by the curette, he remained well for two years, when the disease reappeared on the right temple. This second lesion was of the size of a silver quarter-dollar, and was removed with the curette, followed by the application of arsenical paste. A large ulcer was made, which healed slowly, but the disease has not yet returned. The oldest patient was eighty-eight years old.

There were no cases among the negroes, who are more subject to the deep-seated form of this disease. Fifteen cases were in males and thirty-eight in females, a reversal of the rule, as the disease is commonest in men.

“ eighty and ninety years.....	1
Total.....	53

*Erythema.*—A variety of affections are classed under this heading, including simple localized, idiopathic erythema, erythema multiforme, erythema nodosum, and certain

\* *Loc. cit.*

other forms, such as erythema intertrigo and a number of rashes due to the application of irritants to the skin. Erythema multiforme constituted the majority of the cases, while erythema nodosum was seen in but one patient.

Of the fifty cases of this affection recorded, there were twenty-one in males and twenty-nine in females.

*Erysipeloid.*—Rosenbach\* describes an eruption due to wound infection with putrid animal matter, and this he has called *erysipeloid*. It consists of a red spot upon the skin which extends peripherally, while the center undergoes involution. It produces a sensation of burning and passes away in two or three weeks without febrile symptoms.

Six cases of this disease have come under my observation, two of them being typical, according to the description given by Rosenbach. In the remaining four, the spot, though circumscribed and clear-cut at the edges, did not fade in the center, at least not before treatment was instituted. This consisted in an ichthyol ointment, as recommended by Elliot,† or in a salve of oil of cade with oxide-of-zinc ointment. Five of these patients were cured after two weeks of treatment, while the remaining one relapsed and was not entirely well for a month. Erysipeloid evidently belongs to the group of erythemas, and closely resembles *erythema annulatum*. Considered from this point of view, it would be classed as an *erythema venenatum*. It is my belief that this disease occurs more frequently in surgical practice than is generally supposed, and that a greater number of cases have not been reported because of the mildness of the attack, coupled, perhaps, with an inability to classify it dermatologically. The surgeon, being satisfied as to its cause and character, has been content to let a simple ointment and Nature do the rest.

My cases were briefly as follows:

CASE I.—Female, aged thirty-two. Cleaning crabs five days ago, and next day noticed inflammation of index finger of left hand. This has spread to the metacarpo-phalangeal joint, and presents a circumscribed, convex border. Eruption is very itchy, and at times burns and pains.

CASE II.—Female, aged forty. Eruption located at root of left index finger. Began one week ago after she had scratched her hand while preparing food for cooking.

CASE III.—Male, aged thirty-eight. Eruption on back of left thumb. Drives a garbage-cart and bruised his hand while shoveling garbage.

CASE IV.—Female, aged thirty. Scratched her hand twelve days ago while cleaning crabs. Hand was painful same night, but eruption came later. Eruption located around root of thumb, and is painful.

CASE V.—Female, aged twenty-six. Duration three weeks. Cut left hand while slicing raw meat. This was followed in two days by a circumscribed, itching erythema of palm and back of hand.

CASE VI.—Female, aged forty-five. Cut left hand in fold between index and middle finger while peeling vegetables. On the second day after this the eruption appeared. This has circular, well-defined edges, and is paler in the center than at the periphery.

*Herpes.*—There were seven cases of herpes simplex, two of them occurring on the prepuce—*herpes præputialis*. The remainder appeared about the mouth.

The cases of herpes zoster were thirty-four in number, and were distributed as follows:

TABLE IV.

*Cases of Herpes Zoster.*

Zoster facialis.....	5
“ cervico-facialis.....	2
“ cervico-brachialis.....	2
“ collaris.....	2
“ pectoralis.....	16
“ abdominalis.....	4
“ lumbo-femoralis.....	2
“ sacro-femoralis.....	1
Total.....	34

One of the cases of zoster facialis involved the mucous membrane of the mouth. The patient had taken Cayenne pepper for colic, followed by senna and salts, and experienced the next day a burning sensation in the mouth. On the third day the eruption appeared on the right side of the nose, spreading to the cheek, the right eyelids swelling at the same time. When seen by me, seven days afterward, the nose was red and discharging mucus, the right cheek was swollen, and the lacrymal glands occasionally discharging a tear. On the upper and lower lips to the right of the median line, and on the right side of the hard and soft palates, were a number of small, painful ulcers.

A second case is one of double zoster. The patient was a white man, thirty-one years of age, who had been treated by me for syphilis a year before. The grouped vesicles first appeared on the left side of the abdomen, extending down over Scarpa's triangle and on to the pubes. A few hours later another grouped eruption, but of papules instead of vesicles, appeared on the right side over the sacrum, extending down over the great trochanter to the thigh. A mild ointment was used, and the papular eruption of the right side began to yield to treatment and never formed distinct vesicles. The grouping of these lesions, and the erythemato-papular character of the aborted eruption, together with the pain that accompanied it, leave no doubt in my mind that here was a case of double zoster.

*Leprosy.*—Leprosy, like tuberculosis, is a disease which any one is liable to contract, but which must be acquired under certain conditions. Without pausing to give all of my data, let me state that, in my experience, hereditary disease—that is to say, leprosy in one's parents or grandparents—debility from sickness or alcoholism, certain diets, such as meat, and more particularly salt meat, predispose the patient to this baneful disease. Leprosy does not make a

\* *Arch. f. klin. Chirurgie*, 1887, No. 2.

† *Jour. of Cut. and Genito-urinary Dis.*, January, 1888, p. 12.

woman more infertile than any other wasting disease, though it *does* tend to produce miscarriages or very delicate children. Even this rule has its exceptions, for I have seen leprous women with non-leprous children, who were born after the disease was well marked in the mother. Referring to predisposing causes, the following facts, taken from my histories, will give an idea of the character of the infirmity of which the patient and his relatives were subject, each note being taken from a different case: 1. Stunted growth and mind feeble; is eighteen years old and has not menstruated; breasts and púbes undeveloped. 2. Leprosy appeared just after childbirth—two cases. 3. Old age—is seventy-nine years old; stopped menstruating at age of twenty-nine. 4. Imbeciles; two patients, brothers. 5. Followed measles. 6. Hard drinker. 7. Blind from early childhood, and always feeble. 8. Mother insane. 9. Father died of phthisis. 10. Delicate always. 11. Father insane and uncle epileptic. 12. Followed typhoid fever. 13. Brother insane. 14. Had tape-worm when disease began. I have of late become convinced that one of the ways that leprosy is produced is from animal matter introduced into the system in an uncooked or raw condition.\* My reasons for coming to this conclusion are briefly these:

1. History of having eaten *raw* meat.
2. History of intestinal worms, which are frequently produced by the ingestion of imperfectly cooked meat or fish.
3. Fondness of patients for meat, preferring it greatly to vegetables, and eating it in excess of the latter.
4. Occupation of such a character as to make patient liable to inoculation from animal matter: one was a butcher, one was a rag-picker, and a large majority of the women were either cooks or in the habit of cooking their own meals.

The eighty-three cases here reported were all, with the exception of three, observed in New Orleans, and the patients were residents of the State.† Seventy were white and thirteen were colored; forty-nine were male and thirty-four female. The following tables will illustrate the age and nativity in the cases recorded:

The two patients under ten years old were aged six and nine, respectively. I have never seen the cutaneous lesions of leprosy on a new-born baby. Leprosy produces a marked dyscrasia, but the disease, so far as I am aware, is not inherited in the sense that syphilis is, for example.

It will be seen from Table VII that fifty-seven of my patients were natives of Louisiana and that six were natives of other States, making a total of sixty-three born in the United States. Twenty were born in foreign countries, a large majority coming from Germany.

My records do not give the birthplaces of the parents of all the leprosy patients, but such notes as I have show that twenty-seven of the patients recorded as having been born in the United States had either one or both parents of *foreign birth*.

*Lichen Scrofulosorum.*—The only case of this disease observed is of such interest that it can not be passed over, as it combined the ulcerative scrofuloderm with the papular eruption of lichen scrofulosorum. It is natural that these two affections, due to a common cause, should be found in the same patient, though as a rule this is not the case.

The patient was a white woman, a prostitute, and entered the Charity Hospital on March 8, 1891, with a history of having had considerable flooding three years ago, after an abortion had been produced upon her while she was in the third month of gestation. This left her very weak and anæmic. Her father and mother had both died of consumption, the latter having had the disease only three months.

In August, 1890, the patient had chills and fever with headache, and, on recovering from the attack, her feet were swollen. In the beginning of November she took a hot bath, after which purplish spots appeared over the epigastrium and rapidly spread all over the body, becoming more numerous and deeper in color about the menstrual period.

In the latter part of November the glands on the left side of the neck began to swell, followed in January by the glands on the right side.

On admission to the hospital she was very thin and pale, and presented on the neck, behind the angle of the jaws and an inch and a half below the ears, a swelling from enlarged lymphatic glands, which was covered by bluish-red patches of skin three fourths of an inch wide and two inches and a half long. The outline of the red patches was irregular, and had none of the characteristics of the syphilide. The patch on the left side was open, discharging a purulent liquid. Besides these patches, there was a papular eruption all over the body, except the head and hands, which consisted of minute red papules in small groups, each group being about half an inch in diameter, its outer papules blending it somewhat with adjacent groups; but

this grouping was quite distinct. The eruption was deeper and thicker on the legs below the knees. It did not itch. A close examination of the lesions showed that some of the papules were raised and acuminate and covered with fine scales, while others were flat, some seeming to be slightly below the level of the skin and probably undergoing involution. Those on the legs, if observed alone, might easily have been mistaken for purpura simplex.

This case was under observation about twelve weeks, and during this time the eruption faded or grew deeper several times, owing to the absence or presence of the menstrual flow. The ulcerated glands in the neck were removed under chloroform by Dr. J. D. Bloom, and the glands sent to the pathologist of the hospital, but I have never heard whether or not the bacillus of tuberculosis was found. Erysipelas set in and retarded recovery from the operation, but when this had passed off the patient improved rapidly, leaving the hospital much better, though not yet cured.

*Lupus*.—Two varieties of this disease are generally recognized—*lupus erythematosus* and *lupus vulgaris*—though I must confess that I have never seen very much resemblance between them beyond the fact that both are circumscribed lesions occurring usually on the face.

Four cases of erythematous lupus were treated by me, three of the patients being white and one colored, while two were males and two females. The location in all of them was the face. All but one yielded readily to the curette, followed by a pyrogallie-acid ointment. The one that did not yield would improve for a time and relapse, looking as badly as before.

Of the patients with *lupus vulgaris*, which is now generally recognized as a form of tuberculosis of the skin, one was white and three were colored.

Three of these cases were of the warty variety—*lupus verrucosus*. One consisted of a well-defined patch on the back of the left hand in a mulatto aged twenty-eight years.

The second case was that of a white man aged thirty-two. The papillomatous growth appeared as large, ringed patches on the legs below the knees. These rings spread entirely around the legs, meeting in the rear, leaving the centers smooth, hard, and mottled in color, causing the growth to present the appearance called by French writers *lupus scléreux*.

The third case presented exactly the same appearance as the second, except that it was in a colored boy and located on the face and neck.\* None of my cases were ulcerative—*i. e.*, the so-called *lupus exedens*, a name which is very confusing, as persons afflicted with the ulcerative syphilitic of the nose, or with epithelioma of that organ, have been sent to me more than once as having *lupus exedens*.

*Pediculosis*.—This disease, due to one of the three varieties of pediculi or lice—namely, the *Pediculus capitis*, *Pediculus corporis*, and *Pediculus pubis*—is found usually in filthy and unkempt persons, and frequently is accompanied by an extensive dermatitis or artificial eczema. Sometimes, however, very cleanly persons may be afflicted with these little pests, as in a case of a young lady observed by me, who had considerable irritation of the eyelids after having re-

mained two days on a sleeping-car. An examination with a magnifying glass, and afterward with the naked eye, disclosed the presence of large numbers of the *Pediculus pubis* adhering to the lashes near the eye.

Another case was that of a young lady who was constantly troubled with very itchy erythematous patches on the back of the neck and shoulders. I was able after a long examination to discover a few nits, or ova, in the hair, and cured the disease with antiparasitics. After some months she returned to me with the same trouble, which she had acquired on returning to her room after a summer spent elsewhere. The majority of my cases of pediculosis capitis were in females, probably on account of the greater length of the hair in women and the greater amount of shelter thereby afforded the insect, while the majority of my cases of pediculosis corporis were in men.

The skin of the negro is not so tempting to the pediculus as that of the white man, and the two negroes recorded as afflicted with this disease were half white. I have never seen a case of pediculosis capitis in the genuine African, and believe that these people have an immunity to some extent from the disease. The ninety-two cases of pediculosis observed constitute 4.6 per cent. of the cases recorded.

*Pompholyx*.—Though only two cases of this disease were observed, it is my desire to record one of them for comparison with the cases of dysidrosis already considered.

Mr. J. H., aged forty-seven, consulted me February 7, 1887. Patient had an iliac abscess opening at Poupart's ligament. He had been afflicted with this about eighteen months and greatly weakened by it. Eleven years ago an eruption appeared in the spring-time at the tips of the first three fingers of each hand, and continued to come at this season for four successive years, lasting twenty or thirty days each time. During succeeding years the eruption spread to the other digits, and finally to the palms. When the eruption is present it makes him exceedingly nervous in his already weak condition, and he has resorted to large poultices to relieve the intensity of the itching. When observed by me his hands were swollen and covered with vesicles and blebs, the former being sunk deep into the skin and resembling sago grains. They were located chiefly on the tips of the fingers and the outer edges of the palms, while on the palms and on the finger joints nearest the palms were large, loose blebs filled with a sero-purulent fluid which the patient was at the moment busily removing. A few blebs and vesicles were on the back of the hands. I ascertained that during the past year the eruption had come at irregular intervals, appearing every three or four months and lasting from two to six weeks. It was evident, then, that the debility produced by the abscess had aggravated the eruption. A salve composed of salicylic acid, carbolic acid, and diachylon ointment was used, giving great relief, and in two weeks the eruption had passed away, leaving a smooth, red, scaling surface. During the two years that ensued the eruption appeared some eight or ten times, always relieved by the ointment. Finally it disappeared, and has not troubled him since, though the abscess is not yet cured.

*Pruritus*.—This affection, consisting of cutaneous itching without eruption, was found in fifty-seven white and four colored patients, while the sexes were nearly equally divided. In many of these cases torpidity of the liver was doubtless the exciting cause, as they were relieved by small doses of calomel.

\* This patient reacted strongly to a subcutaneous injection of *tuberculin*. See *New Orleans Medical and Surgical Journal*, June, 1891.

It is a well-known fact that jaundice produces itching, but there are certain cases of intense itching not accompanied by this symptom and in which malaria seems to be the exciting cause. This variety of pruritus may occur in patients whose chills and fever have been broken for some time, or in others in whom the malarial poison lies dormant; but the rule is for a cure to be effected by large doses of quinine. I have treated nine cases of this character, and others of doubtful origin, and have been in the habit of describing this disease to classes of students as *pruritus malarie*.

*Psoriasis*.—None of the thirty-seven patients with psoriasis were negroes. Twenty-five were males and twelve were females. All the varieties of psoriasis were represented in these cases save the *p. annulata*, the *lepra* of Willan. Nothing special was observed with reference to this disease save its utter rebelliousness to arsenic, a remedy supposed by some to be a specific in psoriasis.

Psoriasis constituted 1.8 per cent. of the total number of cases recorded.

*Scabies*.—Out of one hundred and ten cases of scabies recorded, one hundred and four were in white persons. Eighty-four were in males and twenty-five in females. Scabies, though due to an animal parasite, was found in a much more refined class of people than pediculosis. This disease constituted 5.9 per cent. of the diseases observed.

*Syphiloderma*.—In private practice the early and late lesions of syphilis were about equally divided, but at the hospital nearly all were late manifestations, the early ones being relegated to the venereal wards.

Of the two hundred and fifty-nine cases recorded, two hundred and thirty-six were in white persons. One hundred and sixty-three were in males and ninety-six in females. Syphilis constituted 12.8 per cent. of the total number of cases recorded. Three cases of chancre of the lip were observed, in two the lesion being located on the lower lip, and in the third case upon the upper and lower lip—a double chancre. A case of chancre of the cheek was treated. The lesion was about two inches in front of the right ear, and was regarded by me for nearly a week as a furuncle which had not "pointed." On making an incision into it a small amount of pus exuded from a honey-combed tissue exactly like that found in carbuncle. In the mean time the neighboring glands had become swollen and indurated, exciting my suspicion, when I ascertained that the patient, who was a lady of refinement, had wiped upon a towel several weeks before which had been used by a gentleman visiting her house, who had had some sort of skin disease. In due time the eruption appeared, confirming my tardy diagnosis.

*Tinea*.—Only one case of *tinea favosa*, or favus, was observed. It was in a Jewish girl, eleven years of age, born of Sicilian parents.

Fifty-eight cases of *tinea trichophytina*, or ringworm, were observed—nine being ringworm of the beard; seven, ringworm of the scalp; seventeen, ringworm of the body and face (*tinea circinata*); and twenty-five, ringworm of the pubes and thighs (*eczema marginatum*). This latter, in sev-

eral cases, extended as far down as the foot, and in others spread on to the abdomen and the axillary region.

Thirty-nine males and nineteen females were afflicted with this disease.

Ringworm constituted 2.86 per cent. of the cases of disease here reported.

There were twenty-six males and ten females affected by *tinea versicolor*. This eruption in the negro is of a lighter hue than that of the skin.

## LONGEVITY OF THE TUBERCLE BACILLUS.

A CONVENIENT AND RAPID METHOD OF COLORING THE ORGANISM.  
THE EFFECTS OF SOME OF THE STRONGER ANTISEPTICS  
ON ITS CHEMICAL DECOMPOSITION.\*

BY HENRY HEIMAN, M. D.,  
PHYSICIAN TO THE OUT-DOOR DEPARTMENT OF MOUNT SINAI HOSPITAL.

It is not my purpose to present to you an exhaustive paper on the tubercle bacillus. Voluminous literature has been published from a bacteriological, hygienic, and, of late, especially from a therapeutical standpoint. It is my purpose to present to you a few observations regarding—

1. The length of time which this bacillus may be exposed to ordinary temperatures outside the body without losing its staining possibilities.

2. Concerning the most rapid and convenient method of staining.

3. The effects of some of the stronger disinfectants on the tubercle bacillus.

The duration of my labors dates back to January 15, 1891. In the month of March, 1891,† a similar paper was published by Dr. A. K. Stone, of Boston. My paper may seem to you a repetition, or at least a corroboration, of his painstaking and competent labor. My work was, however, done in my office and without the aid of a properly appointed laboratory. Being many times questioned as to the possibility of staining specimens days, weeks, or months exposed, I could give no positive answer. The different coloring agents which I used for staining I shall hereafter mention.

In order to give you a more rapid and comprehensive way to look over the numerous examinations made as to the length of time we are enabled to color the tubercle bacillus, as given to us for examination, and thus exposed to ordinary room temperature, I have deemed it appropriate to tabulate my work.

In viewing the result which I have obtained, you will at first be impressed with the fact that in no single instance have I failed to find the tubercle bacillus after having once determined its presence. Moreover, your attention will be called to the varying number of bacilli found in some of the same specimens. In order not to discuss the last question at great length, I can only say that we can advance numerous theories to account for this variation, the one most plausible to my mind being the drying process of the sputum, forcing out its watery constituents, and leaving be-

hind as sediment the solid materials, including the tubercle bacilli. Their number on that account varies in an inverse ratio to the bulk of the sputum left and also to the mechanical means employed in selecting the sputum to be spread upon the slide. In the supernatant fluid I have not been able to find any tubercle bacilli.

We must also consider that the constant decrease of tubercle bacilli in some of the specimens is entirely due to the continuous withdrawal of tubercular material and also because tubercle bacilli only grow or multiply at blood

temperature, and in more favorable culture media than ordinary expectorations. The oldest specimen, which I first stained successfully on March 5, 1891, has been in possession of Dr. E. Friedenbergs for more than a year, and still after twenty months have elapsed I have found tubercle bacilli each time in sixteen examinations. Now, in order to rule out the possibility of tubercle bacilli having fallen into my phials, I have kept non-tubercular sputum amidst all the tubercular ones, one bottle even uncovered, but after repeated examinations have not been

able to find any tubercle bacilli in the control bottles. As far as finding the tubercle bacilli in the sputum of non-tubercular patients, I have also in the specimens which I have examined obtained a negative result. This work, however, has been fully studied by Koch\* in his master-work, and by Fraentzel and Balmer† and Ziehl,‡ who have also, after numerous examinations, been unable to detect the tubercle bacillus in the sputum of non-tubercular patients. The finding of *living virulent germs* even in dry sputum after such length of time, as Dr. Stone has shown, I consider a most important practical point. Cornet,§ by his numerous experiments, has vividly and justly called our attention to this matter, especially from a hygienic standpoint—the importance of preventing the spread of tuberculosis by simply placing water in the cuspidors. We can only conclude, from the results obtained, that the tubercle bacilli under ordinary environments retain a longevity similar to the other bacteria, due to their true spore formation. I have seen Koch demonstrate a pure culture of anthrax bacilli still retaining their virulency after eighteen years.

As regards the changes undergone by the tubercle bacilli || in course of time, they seem to me to be that they did not take on the coloring agents as well [Ziehl's solution], and that they appear of a more brownish color. To determine the presence of the tubercle bacillus in local tuberculosis, I have examined the discharges of forty cases, including joint disease, cold abscesses, and scrofulous glands. Eighty specimens were prepared. Only in one—that coming from a cervical (cheesy) gland—I have found the germ. I firmly believe in their presence in all the other aforesaid affections. Koch ^ mentions three cases of freshly extirpated scrofulous glands, in two of which the tubercle bacillus was found. Out of four cases of tubercular joint disease, its presence was detected in two. It is a well known and recognized fact that we rarely find them in pus, but generally in cheesy concretions. Dr. Kanzler ¶ reports thirty-one cases of scrofulous glands, finding the tubercle bacillus fourteen times in two hundred and thirteen prepared slides. Thirteen cases of bone tuberculosis with eight positive results.

Concerning the most convenient and rapid method of staining the tubercle bacillus, I shall not describe the various methods known, or those which I have employed. Suffice it to say, Koch's,‡ Ehrlich's,§ Biedert's,¶ and Gram's\*\* were used for some of my specimens. For over four hundred of them, however, I have employed Friedländer's method, as described by Dr. M. Manges,†† and, on account of its simplicity, I was prompted to undertake this labor. Its application insures cleanliness, rapidity, efficiency, and little

expense. Methylene blue is used as the differential coloring. I, however, substitute malachite green, because of its property of coloring the specimen more intensely and quickly, at the same time differentiating the red colored bacillus as well as is done by the methylene blue. The disadvantages of Friedländer's method, however, consist in the manner of spreading the sputum on the slide and the continuous and exposed friction causing it to dry with great rapidity, thus separating numbers of little particles, and in this manner jeopardizing our own respiratory apparatus. Weichselbaum\* has clearly proved that after inhalations of tubercular sputum, tubercles were found in the lungs, also in other organs. May this point be a special warning to those examiners predisposed to tuberculosis. I have stained and examined slides with this method in six minutes' time, especially if the sputum be old. For your convenience I shall briefly quote this excellent method. Special attention I have paid in all my work never to use an old slide. Thus I exclude one possible error. In collecting the sputum in a small wide-mouthed bottle, I have never required the transfer of it into a watch-glass. The solutions used for this method are :

1. *Ziehl's Fuchsine Solution :*

Fuchsiue.....	1·0 ;
Alcohol, 95 per cent. ....	10·0 ;
Sol. acidi carbolici, 5 per cent.....	100·0-

2. *Decolorizing Solution :*

Nitric acid.....	5·0 ;
Alcohol, 95 per cent.....	85·0 ;
Distilled water.....	15·0.

3. *Differential Staining Solution.*—Concentrated aqueous malachite-green solution, prepared by taking an excess of malachite green ; add to distilled water, allow it to stand for two days, then filter.

Now clean the slide ; sterilize it by passing slowly through flame. With a sterilized platinum hook select sputum and spread it in the center of the slide to the size of a one-cent piece until dry. As slides require longer to become heated, pass them through a flame quickly ten to twenty times add with a pipette fifteen to twenty drops of Ziehl's solution, which amount protects the separated particles. Allow this solution to act about five minutes, then hold the slide with swaying movements over a small alcoholic or Bunsen flame until the specimen steams ; wash off with water, and dry with filter paper. Now add the decolorizing solution, to act on it about thirty seconds, or rather until all the red color disappears. Wash off and dry again with filter paper. Finally cover with a few drops of the concentrated aqueous malachite-green solution for about five to ten seconds. Wash off and dry with filter paper. The specimen is now made ready for examination by placing one drop of cedar oil on it. For permanency first add one drop of Canada balsam and a cover glass. In the beginning this method may appear discouraging, but after a few trials a pretty even surface of the sputum on slide will be obtained. On this our success depends.

As to the effects of some of the stronger disinfectants

on the tubercle bacillus, I must confess that my experiments were few and partly unfinished, because of the disadvantages under which I had to labor. To carry out this work properly, one must make biological experiments, and direct inoculation of animals, for which a complete laboratory is essential. I have confined myself only to the use of some of the stronger disinfectants, and their action on the tubercle bacillus, as far as the microscope reveals to us. Koch \* has already shown that the tubercular sputum, even in a dry state, after two to four or eight weeks, still retains its virulence, but finally the organisms die or become transformed into spores, and then lose their coloring property. The cadaver will certainly take on coloring agents up to the time it becomes chemically decomposed, which I believe to be able to demonstrate to you in cases of the disinfectants I have used. A five-per-cent. carbolic solution does not destroy them chemically, for we employ it in our Ziehl's solution. On that account I have employed a ten-per-cent. carbol-glycerin solution, with the result of staining the tubercle bacillus. Schiller and Fischer, † in their experiments with disinfectants, have proved by inoculations that tubercle bacilli were killed by a three-per-cent. carbolic solution in twenty hours. A. Yersin, ‡ a French observer, reports having killed them after heating for ten minutes up to 70° C. Pampukes, § in Athens, heated them up to 120° C., obtaining the same results, though still taking on the coloring agents. I applied sublimate solutions (1 to 1,000 and 1 to 500), and after either solutions, well mixed with tubercular sputum, I have been enabled to color the tubercle bacillus. Their resistance to such great heat and rather strong disinfectants indicates to us the kind of disinfectants we ought to employ in order to destroy them chemically.

As the last and strongest disinfectant, I applied chlorine solutions—twenty-five per cent., fifty per cent., and in a concentrated form. In none of the specimens, after the use of these strong solutions, have I been able to determine the presence of the tubercle bacillus, nor other organized elements of sputum. Notwithstanding the disagreeable and pungent odor of chlorine, it certainly bears to-day the name of one of our most efficient disinfectants for such dangerous germs.

May the publication of this paper be especially of some aid to the general practitioner, who may be far distant from his colleague who is practicing clinical microscopy. The physician can instruct his patient to expectorate directly into a small, sterilized, wide-mouthed bottle, with a cotton-covered cork. It is best to collect the first sputum raised in the morning, as in day-time the large amount of mucus formed dilutes the specimen. In this manner sending it for examination, the same result will be obtained as if examining the sputum directly after expectoration. To Dr. B. Stiefel I must extend my sincere gratitude for his able assistance in this work.

## PRIMARY RHEUMATIC ENDOCARDITIS WITH ERYTHEMA NODOSUM.

By C. G. CHADDOCK, M. D.,

TRAVERSE CITY, MICH.,

ASSISTANT MEDICAL SUPERINTENDENT OF THE NORTHERN MICHIGAN ASYLUM;  
FELLOW OF THE CHICAGO ACADEMY OF MEDICINE.

THE following case presents several features of interest and importance with reference to diagnosis, and it shows a distinct relation between rheumatism and erythema nodosum that is not sufficiently appreciated:

On October 4, 1891, W. P., a young man aged eighteen, consulted me concerning a cough that had troubled him for nearly two weeks. I was thoroughly acquainted with his previous health and habits, as well as with the fact that he was working in a basement where light and ventilation were bad. Some weeks before, a sister, six years older than himself, had died of pulmonary phthisis. On September 27th, a week before I saw him, his lungs were examined by a colleague, who found the breath-sounds of the right apex equivocal, and was inclined to fear incipient phthisis. In the week before he came to me he had lost nine pounds in weight. When I examined his lungs I found the condition that had been described to me by my colleague. The heart-sounds were without murmurs; there may have been accentuation of the pulmonary second sound at that time, but I failed to discover it. The apex-beat was in a normal position, and the superficial cardiac dullness was not increased. The pulse was full and regular at 80. During the examination he coughed frequently, but there was no expectoration and had been none. His subjective symptoms were a general feeling of malaise, indefinite pains through the chest, shortness of breath, annoying thirst, and chills at times followed by what seemed to him mild fever. For more than two weeks he had had night-sweats. According to his statement, his illness had begun on the night of September 21st, when he woke up to find himself perspiring very freely. He was never in better health than just before this illness.

Temperature on the evening of October 4th, 101° F. A diagnosis of incipient phthisis seemed all but justified, and prescriptions with this view were made.

The patient had been working up to that time. Rest was enjoined. The temperature reached 102° F. the following evening, and on the evening of the 6th it was 103° F.: and examination of heart at that time revealed a soft systolic murmur at the apex, with accentuation of the second sound of the pulmonary valve. The following morning the murmur was again heard. The thought that this murmur was hæmic did not seem entirely satisfactory, and rheumatic endocarditis suggested itself as its cause. The suspicion of rheumatism led to careful examination of joints, and revealed no anomalies; but on the front of each leg were found six spots of erythema nodosum, which varied in size from a quarter to half an inch in diameter. These spots were excessively painful on pressure. The patient had noticed them the day before, but had failed to speak of them, owing to the fact that they caused him no pain save when he touched them. This discovery, with the systolic mitral murmur, led to the diagnosis of rheumatism, and the treatment recommended by Dr. Latham \* was undertaken. The diet was restricted, and seventy-six grains of salicylic acid were given during the afternoon. The result of this was an evening fall of temperature to 98° F., and a slowing of the pulse to 64, while all tenderness of the spots of erythema was removed. Slight hebetude was also induced. There was annoying breathlessness on attempting to rise in bed, and absolute rest was enjoined.

\* *Lancet*, 1886, vol. i, p. 818.

October 8th.—Temperature at 8.30 p. m., 98° F.; pulse, 56, with hesitancy of the beat. Thirteen grains of salicylic acid during the day. Cough less troublesome.

9th.—Right ankle very painful; some swelling and great tenderness over front of joint. Temperature rose to 102.4° F. at 6 p. m. Seventeen grains of salicylic acid during the day. The cardiac murmur was very distinct at apex and there was marked reduplication and accentuation of the pulmonary second sound, the reduplication of second sound being heard also at apex. It was evident that the left ventricle was undergoing hypertrophy. The apex-beat had reached the mammillary line in the fifth interspace, and the heaving could be seen in both the fourth and fifth interspaces. The cardiac dullness had increased, but there was no dullness to the right of the sternum. The spots of erythema were still distinctly red, but were only slightly tender.

10th.—Both shoulders and both elbows stiff and tender. One tender spot of erythema nodosum over middle of spine of right scapula. Several similar spots on back of neck; one back of left ear. Several red herpetic spots on left side of neck; all tender on pressure. Reduplication of second sound at apex no longer heard. Temperature reached 104° F. Pulse, 72, with slight irregularity and some hesitancy of beat. Thirty grains of salicylic acid during the day. The temperature chart shows the subsequent events of fever and pulse.

From October 11th, forty grains of salicylic acid were taken daily until the 15th, when the amount was increased to fifty grains; and this daily dose was continued until the 23d, when it was reduced to thirty grains. This dose was continued until the 26th, when it was reduced to twenty grains, and finally discontinued on the 30th.

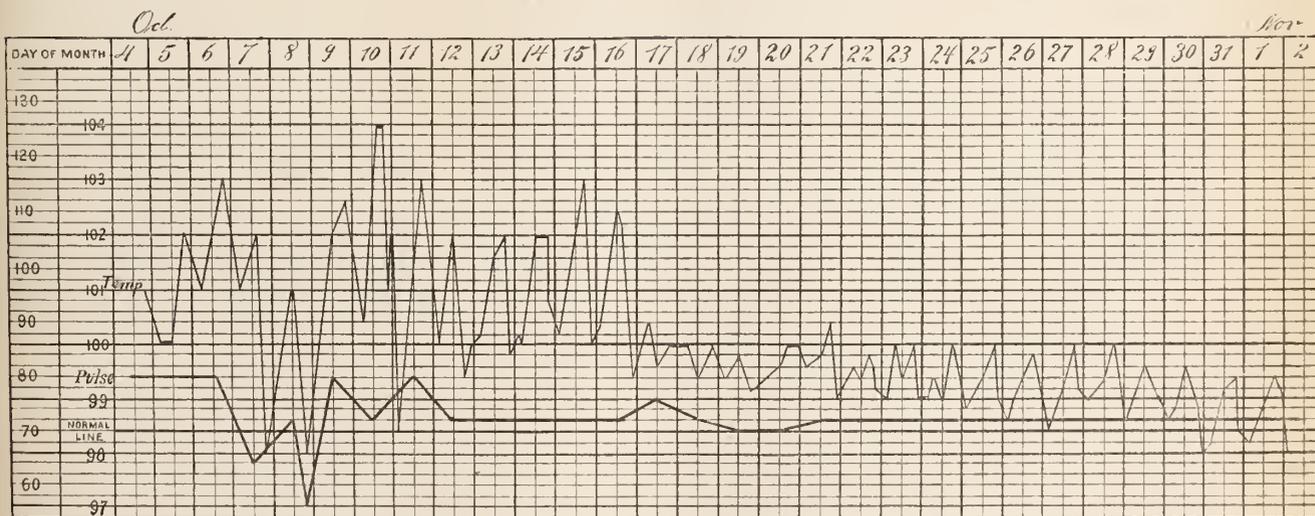

During treatment the bowels were moved almost daily with calomel and salines. The tenderness of shoulder and elbow joints disappeared on the 12th, but the ankle continued painful until the 26th. On the 22d it is noted that the erythema is gone, save for a few spots on back of neck. There was some desquamation of the spots on the neck. There were two spots on the dorsal surface of left hand half an inch in diameter that were herpetic in character. Sweating occurred occasionally at night during the illness.

may be seen in the fourth, fifth, and sixth interspaces. No dullness to the right of sternum. Pulse regular, full, and strong at 72. During the last two weeks of the illness there was no cough.

It should be added that there is a strong hereditary predisposition to rheumatism. On both the father's and mother's side there is rheumatism, and the patient's brother passed through a severe attack.

The actual duration of the disease was forty two days, but the symptoms were not such as to induce the patient to consult a physician, though several were immediately at his service, until a week had elapsed, and then actual treatment was postponed for a week more, owing to uncertainty of diagnosis. The symptom that was earliest to appear and most troublesome was dry cough, and this was due to pulmonary congestion, not to incipient phthisis. When the diagnosis of endocarditis was made there was no other evidence to support it than the mitral insufficiency with fever. At no time were there any subjective cardiac symptoms; at no time was the cardiac rhythm seriously altered. The discovery of erythema nodosum, occupying its favorite seat, made it seem, with the strong existing predisposition, almost certain that the malady was of a rheumatic nature, and salicylic acid was given. The medicine altered the condition of the erythema at once, but it did not prevent the development of the joint affection, though the joints involved were never so much affected as to cause the patient suffering. With the advent of these symptoms there could no longer be any doubt about the correctness of the diagnosis.

In this case the erythema nodosum developed subsequently to the endocarditis, but before the joint affection, and it formed a prominent feature of the disease. It was not due to the acid, for it was present before that medicine was exhibited; but it was affected by it—made less painful. Those spots that developed during the exhibition of the acid were less painful than the first eruption had been, and showed a herpetic tendency with ultimate desquamation. Certainly, erythema nodosum should be assigned a place in

27th.—The temperature reached normal without medicine (antifebrine had occasionally been given), and on November 2d there was an absence of fever.

Condition of the heart on November 1st: Soft mitral regurgitant murmur heard at apex; second pulmonary sound much accentuated; apex-beat in fifth intercostal space half an inch outside mammillary line. The heart-beat is very diffuse and

the symptomatology of rheumatism; even one case like this goes far to confirm the conclusions reached by Mackenzie\* in his study of the relations of rheumatism, cardiac disease, and erythema nodosum.

\* Dr. Stephen Mackenzie. Erythema Nodosum. A paper read before the Clinical Society of London, April 9, 1886.

It is noteworthy that large doses of salicylic acid, with its decided antipyretic influence, had no other effect on the heart than to reduce the number of the beats. It does not seem that the acid exerted any effect on the duration of the fever, but it certainly made the symptoms of the disease, usually so insufferable, quite endurable.

The marked prolongation of the fever after it had ceased to rise above 100° F. is remarkable, and, in the absence of any other explanation, may be ascribed to the continuance of an inflammatory condition of the endocardium. The patient is now convalescent and shows but slight etiolation, though he lost sixteen pounds in weight.

## ON THE OPERATIVE TREATMENT OF DIVERGENT STRABISMUS.\*

BY EMIL GRUENING, M. D.

ABSOLUTE divergent strabismus is so often associated with high degrees of myopia, with anisometropia, or with monolateral amblyopia, that these conditions are regarded as causative in the development of the muscular anomaly in question. Not infrequently, however, this very form of squint is observed in persons whose two eyes are emmetropic and equal in vision. In divergent strabismus the range of motility is normal; both in the squinting eye and its fellow the inner edge of the cornea touches the caruncle upon extreme adduction, and the outer edge of the cornea the outer canthus upon extreme abduction. The power of accommodative convergence is lost. In some cases the degree of divergence changes with the position of the object, the deviation being more pronounced in distant than in near vision. There is no tendency to use both retinae for the binocular act of vision for any position of the object.

These characteristic features are pointed out here because, for the purpose of this paper, it is necessary to exclude on the one hand the various forms of periodic divergence, and on the other hand all forms of divergence known as secondary, parietic, and paralytic.

The latter go to make up separate classes of deviation, are recognizable by limitation of motility inward, and require for their correction the operation of advancement. The ordinary divergent squint, on the contrary, shows no limitation of motility and can be corrected by simple tenotomy of both recti externi muscles. In many of our recent text-books of ophthalmology the various forms of divergent squint and the operative methods applicable to their relief are somewhat commingled. As a consequence of this intermixture of classes and measures, the following proposition is induced: "Tenotomy of the recti externi muscles generally proves insufficient for the correction of absolute divergent strabismus." Yet the reverse is true. If by absolute divergent strabismus the so-called concomitant divergent strabismus is understood, the proposition should read: "Tenotomy of the recti externi muscles, with the addition of

an adducting suture, generally proves sufficient for the correction of divergent strabismus.

In the past ten years I have practiced this operation with the greatest satisfaction in all my cases of absolute divergent squint, and of many I possess a detailed record. Some of them remained under observation a number of years—a sufficiently long time to permit me to say that the favorable results were not only immediate, but also permanent. It is now almost forty years since Albrecht von Graefe wrote that the precautionary measures so essential in tenotomy of the rectus internus did not apply to the rectus externus, inasmuch as a free division of the conjunctiva over the externus and of the muscle itself could cause neither an unsightly recession of the caruncle nor a vexatious limitation of motility. These considerations guide me, and in my operations the conjunctiva is freely incised and the whole extent of the tendon and its insertion exposed. Both recti externi are operated upon at one sitting. In cases of divergence of not more than two millimetres the tendons are divided at their points of insertion. Whenever the deviation measures more than two millimetres, the tendons are divided at a distance from their insertions, the distance corresponding to the degree of squint.

Thus, in a case of divergence where the measurement by corneal reflex, according to Hirschberg, showed a deviation of five millimetres, both tendons were divided at that distance from their points of insertion. The tendinous stumps are not removed. The conjunctival wounds are closed by a few interrupted sutures placed horizontally. A silk thread is passed through the conjunctiva over both interni muscles in a line with the horizontal meridian of the cornea and tied over a pledget of cotton on the bridge of the nose. The eyes are thus coupled in a position of strong convergence which is maintained twenty-four hours. A binocular bandage may be applied; it relieves the discomfort caused by the suture.

CONCLUSIONS.—(a) The operation here described yields better results in cases of absolute divergent strabismus than advancement.

(b) It is a simpler operation.

(c) In advancement the graduation of the effect is impossible.

(d) In tenotomy of the externi, the shortening of the muscles in accordance with the degree of squint, though practiced empirically at present, suggests the possibility of attaining mathematical exactitude in the graduation of the effect.

## ON TANNATE OF MERCURY.\*

BY S. LUSTGARTEN, M. D.

I HAVE to express my thanks for the opportunity extended to me of giving my views in this learned society concerning the subject upon which Dr. Allen has dwelt in so elaborate a manner. This opportunity is so much

\* Read before the American Ophthalmological Society at its twenty-seventh annual meeting.

\* Read before the Section in Genito-urinary Diseases of the New York Academy of Medicine, December 10, 1891, in the discussion of Dr. Charles W. Allen's paper on the same subject.

more welcome as, since I first brought the tannate of mercury before the profession, in 1884,\* I have not communicated until now my further experiences with this preparation. In spite of the latter circumstance, the tannate has now many friends, although a marked predilection in some countries for the hypodermic treatment has not been favorable to more extensive and unprejudiced trials of internal methods in the treatment of syphilis. To the list of authors who speak favorably of the preparation in question I could add several more—such as Campana, Doruig, Epstein, Lane, Monti, Zeisler. Furthermore, the *hydrargyrum tannicum oxydulatum* was made about three years ago an official preparation of the Austrian Pharmacopœia.

What gives this preparation a remarkable position is its peculiar chemical reactions. As it is not acted upon by dilute acids, it will pass the normal stomach without any symptoms whatever. As soon as, in the duodenum, the reaction changes to an alkaline one, it is reduced to exceedingly small globules of metallic mercury—so small that a direct absorption in this state, by the *villi* of the small intestines, is imaginable. That is the reason why, in my original publication, in discussing this point, I ventured the expression, “*internal inunction.*” It is indeed highly probable that the chemical process, which finally brings about the solution of mercury and its entrance into the circulation, is the same with the metallic globules of the gray ointment in the skin and the reduced particles of mercury of the tannate in the intestines. That would account for the satisfactory therapeutic action and for the freedom from irritation of the latter. Although, in a small minority of cases, irritation of the bowels has been recorded, it is still generally admitted that the salt in question is a comparatively mild and non-irritating one.

I have proved the presence of mercury in the urine within twenty-four hours after the administration of the tannate. In an elaborate series of quantitative examinations of the urine in different mercurial treatments, Winternitz † has found the largest amounts after injections with insoluble mercurial compounds, and the smallest after internal treatment, among others, with the tannate. Inasmuch as the internal medication shares the same fate with the inunctions, which I, with many others, think to be, if properly applied, the most energetic treatment, these interesting experiments prove once more that theoretical views are not always in accordance with the facts derived from practical observations.

There are two methods for the manufacture of the tannate of mercury—a wet and a dry process. The former one, which I used myself in my first experiments, consists in precipitating a concentrated solution of tannic acid by freshly prepared oxydulated nitrate of mercury, dissolved in water, and drying the precipitate at a low temperature. The second consists in rubbing together tannic acid and oxydulated nitrate of mercury, washing and drying. The more expensive wet process gives, as wet processes in general do, a preferable preparation, consisting in an impalpable powder, free from nitric acid, which guarantees a quicker and more complete absorption. Such a preparation, manufactured by G. Hell & Co., Troppau, Austria, is mostly used in Austria. The French tannate is prepared in a similar manner, while Merck's drug is obtained by the dry process.

My experience extends to about three hundred cases. It would take too much time to develop my views concerning the treatment of syphilis, so I shall confine myself to describing the rôle which the tannate plays. I am an adherent of a modified intermittent treatment. In this treatment, in order to bring about the most favorable results, it is of the greatest importance that the first treatment after the appearance of the secondary eruption be as energetic as possible, and, if practicable, it always ought to be a course of thirty to forty inunctions. The subsequent treatment consists in the administration, for one month at a time, of three to five grains daily of tannate of mercury, with increasing intervals of from one to three months.

The tannate has also given me very satisfactory results in the recurrent forms of the secondary stage and in the tertiary stages, where iodide of potassium can be given, if the precaution be taken to leave an interval of several hours between the alternating doses—*e. g.*, in the morning a dose of potassium, three hours afterward the tannate, six hours later another dose of potassium, and before retiring a second dose of the tannate.

The daily dose for adults begins with three grains, and if this is well borne and it be found necessary, it can be increased to five grains or even more. One course of treatment consists of 100 to 150 grains.

The daily dose for adults begins with three grains, and if this is well borne and it be found necessary, it can be increased to five grains or even more. One course of treatment consists of 100 to 150 grains.

In a healthy state of the digestive tract—and only in this case should mercury be given internally—I have never observed symptoms on the part of the stomach, which is only natural, as the tannate, as above stated, does not, in all probability, undergo any change in its acid contents. With regard to the bowels, it is in a minority of cases apt to produce two or three soft passages a day, which is often desirable; in the majority of cases it does not interfere at all. Certain dietetic precautions ought, of course, to be taken, especially with persons given to diarrhœa—such as refraining from fresh fruit, beer, white wine, etc. For years I have refrained from combining with this treatment even the slight doses of opium formerly employed, as the continued use of this drug has seemed undesirable.

I have never had a bad case of stomatitis, as this preparation has no cumulative qualities and as I have watched the mouth carefully and stopped the use of the tannate for a while, upon the slightest appearance of irritation, until these symptoms had disappeared. This is a great advantage of the tannate, especially over the injections of insoluble compounds of mercury with their treacherous stomatitis and other dangerous possibilities. I use the latter only where for some reason the other methods are not applicable or where delay is dangerous, as in syphilis of the nervous system, where it is desired to bring a large quantity of mercury into the circulation at short notice.

The tannate has given me excellent results in the treat-

\* *Wiener med. Wochens.*, 1848.

† *Arch. für Derm. und Syph.*, 1889, 6. Heft.

ment of children in hereditary as well as in acquired forms. I have prescribed in these cases a third of a grain two to four times a day, to be taken in a teaspoon with milk—if feasible, mother's milk.

The formula which I have generally used with adults is the following:

℞ Hydrarg. tannic. oxydulat. . . . . gr. jss. ;  
 Acid. tannic., }  
 Sacch. lactis, } . . . . . āā gr. ¾.

M. F. in pulv. sive in capsul. gelatin.

Sig.: One twice or three times a day.

In America I have used largely, in private practice, the one-grain soluble pills manufactured by W. H. Schieffelin & Co., and have reason to be satisfied with the results.

In dispensary practice, for the sake of economy, I have used the one-grain compressed tablets made by John Wyeth & Brother. Tablet triturates can not be used, as water is necessary for their preparation, which causes chemical decomposition in a short time.

In conclusion, I wish to state that, in my hands, the tannate of mercury has proved a very efficacious and valuable preparation of mercury, comparatively free from unpleasant accompanying symptoms, and I should be loath to dispense with it in the treatment of syphilis.

AMPUTATION OF THE VAGINAL PORTION OF THE CERVIX UTERI IN CASES OF SUSPECTED CARCINOMA.\*

BY ANDREW F. CURRIER, M. D.,  
 NEW YORK.

PERHAPS it would be better to say *provisional amputation*, or "exploratory excision," as Müller styled it in a paper written in 1884 (*Ann. de la Soc. de méd. d'Anvers*, 1884, xlv, 235), the idea being that the operation is to be performed to enable one to complete a diagnosis which is incomplete and unsatisfactory without it. The object of the operation is also to avoid the alternative of removing the entire uterus and finding that the carcinoma was only a suspicion existing in the mind of the operator, which certainly does not magnify the wisdom or judgment of the latter and leaves the patient unnecessarily mutilated, even if she escapes with her life. As has already been intimated, the idea is not a new one, but I am not aware that the operation has been practiced to any considerable extent for the purpose of verifying a diagnosis of carcinoma of the vaginal portion. It is suggested because of the inconclusive results which so often attend the examination of scrapings from the endometrium, and even of small portions of the cervical tissue itself. If a segment of tissue large enough and long enough to reveal the vital condition in the entire length and breadth of the vaginal portion is removed from any except very large organs, in which case amputation or trachelorrhaphy will frequently be indicated whether there

is malignant disease or not, the resulting wound will quite destroy the symmetry and usefulness of the organ and may necessitate amputation, which might better have been determined upon at the outset. With the entire vaginal portion removed, we are in a position to study the extent of the disease, if disease exists, to decide with a greater degree of certainty, by the preparation of many sections, if necessary, as to the virulence of the disease, and either to interfere no further surgically or to perform hysterectomy if the conditions warrant such an operation. To a certain extent the proposition is analogous to that which is meeting with no little approval among general surgeons—namely, to precede resection of the intestine by colotomy.

The position which I take is entirely in harmony with the view which I have held and expressed for years, that upon early diagnosis must we mainly depend for the successful surgical treatment of malignant disease of the uterus. This point can not be too often repeated or too strongly emphasized, and the gynæcologist can not insist too vigorously that the general practitioner should seek advice whenever he finds a patient suffering with a stubborn erosion or ulcer of the mucous membrane of the vaginal portion or with hæmorrhage from the endometrium for which he can not satisfactorily account. But this position is aside from the question of precision in diagnosis, which in many cases will only be attained by the performance of the exploratory or provisional operation to which I have alluded. Excluded from consideration at the present time are all those cases in which the existence of malignant disease is so unmistakable, both clinically and microscopically, that no time need be lost in provisional procedures. For such I would advocate, as I have done for years, the immediate total removal of the uterus and its diseased surroundings, or the palliative operation with scissors, curette, caustic, and cautery, if radical removal is impossible. Two motives have influenced me to the discussion of this subject in a brief paper. The first is that, in common with many other gynæcologists, I frequently see cases which make me suspicious of the presence of malignant disease of the vaginal portion of the cervix uteri. As already stated, the examination of scrapings and bits of tissue in such cases is often very inconclusive, and upon such evidence one should hesitate to recommend to a woman the dangers of a grave operation, the resulting mutilation and deformity, and the interference with important functions. The second is that operations have been performed, uteri and adnexa removed, only to find that there was no serious disease present in the organs. Naturally enough, the history of such cases is never published in all its details, the specimens are seldom shown at our society meetings, and he would be a very courageous or a very ignorant man who would run the gantlet of the criticism which the presentation of such specimens would call forth. But there is no man so acute in his judgment or so skillful in his operative work that he can afford to ignore the lesson which such experiences, real or potential, teach—namely, that careful diagnosis is at the bottom of all good work in the field which is under consideration.

\* Read before the Medical Society of the State of New York at its eighty-sixth annual meeting.

Among the conditions which render diagnosis difficult with reference to the presence or absence of malignant disease of the vaginal portion may be mentioned the following:

1. Endometritis, with or without hæmorrhage from the interior of the uterus.
2. Hyperplasia, with or without fissure of the os and endometritis.
3. Erosions, ulcers, and glandular disease.

In other words, the conditions which must always call for careful attention in connection with disease of the vaginal portion are hæmorrhage, infiltration, and ulceration, and the conditions which are kindred to or suggestive of them.

I. Endometritis is a comprehensive term. In its ordinary acceptance, in which there is merely a catarrhal condition of the endometrium, it does not excite apprehension of any serious pathological disturbance. It is the most common of all the disorders of the endometrium; there are few women who have experienced the pregnant state who do not suffer with it, and I am satisfied that we frequently attach greater importance to it than is warranted by the actual condition of affairs. But if the condition is one of active inflammation, with a constant discharge of pus, or of pus mingled with blood, it is neither simple nor harmless, and calls for serious investigation as to its cause and the proper means for its relief. It may be entirely unaccompanied by pain. There may or may not be a certain degree of debility resulting from the discharge. But in any case the endometrium should be thoroughly curetted, the tissue being scraped away to the submucous tissue, and the scrapings carefully examined. As has already been stated, such an examination frequently shows us nothing but the evidence of an inflammatory process, or it may leave us in doubt whether there is not also the existence of a neoplasm. If after the lapse of a few weeks there is no evidence of improvement, the discharges of pus, blood, and epithelium continuing, we are justified as the next step in the treatment in amputating the vaginal portion, which will yield us material for determining with greater certainty as to the extent of the disease, and we can then decide whether all necessary operative procedures have been adopted, or whether we should take steps of a more radical character and remove the entire uterus. If the disease proves to be purely inflammatory, or is very limited in its extent as a malignant process, no harm will have been done, the uterus will still be enabled to perform its customary functions, and we will have been placed on our guard for subsequent developments. I have known of cases of this kind which have retained their suspicious, semi-malignant character for years which have been held in check by curetting performed at sufficiently frequent intervals, and which have never enabled one to say with certainty that there was sufficient severity of the symptoms to warrant complete removal of the uterus. I have had cases in which the vaginal portion was amputated and in which the microscope showed that the malignant disease was limited to an area well below the plane of section. Of course one must not ignore the fact that the corporeal endometrium may be the seat of disease simultaneously with that of the cervix, perhaps even

to a greater extent than the latter. Such cases unquestionably require the radical operation, and our investigation should not be limited to any one portion of the organ in determining the extent to which it is the subject of a disease process. The endometritis with hæmorrhage which results from abortion, retroflexion of the uterus, and the presence of submucous myomata has not infrequently given rise to the suspicion of malignant disease of the vaginal portion. I have seen illustrations of all these conditions in which such a suspicion was aroused.

II. Hyperplasia of the vaginal portion may be suggestive of the infiltration which accompanies malignant disease. I have seen such a suspicious condition in both nulliparous and parous women. The mucous membrane may be smooth and apparently healthy and the endometrium show nothing abnormal or only a slight catarrhal condition, and yet the unusual size of the vaginal portion suggests the possibility of a neoplastic process. I can recall such a case in a nulliparous woman in which the vaginal portion was amputated more than three years ago, nothing more than an excess of connective tissue being found in the specimen. The body of the uterus is still very large, the patient continues to suffer with dysmenorrhœa, and it is yet undecided whether she is afflicted with a slowly progressing interstitial inflammation or with an adenoma which may yet require radical measures.

In the cases in which there is not only enormous increase in the size and density of the vaginal portion but fissure of the os as well, with eversion of the endometrium, and possibly endometritis and hæmorrhage, the suspicion of malignant disease is often a reasonable one. It is this class of cases, in which the nutrition is so perverted, that suggested to the mind of Emmet years ago the possibility of the development of carcinoma upon such a foundation. I believe that with these conditions such a development frequently does occur. At any rate, amputation should be performed and the diagnosis can then be determined. Amputation, in my experience, is preferable in such cases to Emmet's operation, for though the latter would enable one to obtain a sufficient quantity of tissue for careful microscopic investigation, the depraved character of the tissue is not conducive to good union in case the wounded surfaces are brought together by a plastic operation. Of course this remark applies only to the cases in which the vaginal portion is very large, the fissuring very extensive, and the density of the tissue excessive.

III. Erosions, ulcers, and glandular disease of the vaginal portion are frequently mistaken for malignant disease, but in many cases amputation will not be necessary to complete the diagnosis.

Erosions are sufficiently common, may include only a narrow circle of mucous membrane immediately contiguous to the os uteri, or may present a much more extensive area. The typical erosion, of benign character, is simply an accumulation of granulation tissue, which bleeds easily, like all granulation tissue, is never of spontaneous origin, and frequently disappears when the exciting cause is removed. In the great majority of cases it is caused by the discharge which accompanies endometritis, whether that be pus, blood-

or mucus, and whether the endometritis be the consequence of an abortion, an intra-uterine tumor, or some other lesion of the endometrium. It is occasionally of traumatic origin, as in cases in which coitus has been violent, or in which a large and heavy vaginal portion has rested upon the floor of the vagina and the epithelium has been rubbed off by the movements of the patient. The free hemorrhage which so often accompanies it, with the enlargement of the vaginal portion, which is also frequently present, should excite suspicion. If there is an endometritis or an intra-uterine tumor, the latter should be removed if possible, curetting should be performed, and the latter operation should include the careful scraping away of the granulation tissue forming the erosion. I have seen suspicious cases satisfactorily cleared up by such treatment and the diagnosis of benign disease determined; but if the eroded tissue absolutely refuses to heal, amputation of the vaginal portion will be indicated as the next procedure. Ulceration of the vaginal portion, apart from that which occurs in well-marked cases of malignant disease, may be traumatic, syphilitic, or chancreoidal, rodent and papillomatous. The traumatic ulcer may be the result and extension of erosion, it may follow an œdematous condition of the vaginal portion, to which condition I called the attention of the profession in a paper presented to the American Gynecological Society in 1889, or it may be the result of violence from various causes. The syphilitic or chancreoidal ulcer is not of frequent occurrence and should depend for diagnosis upon the data by which venereal sores are identified in other locations. The papillomatous ulcer, or *papilloma verrucosum*, was described by Heitzmann in 1887 (*Allgemeine Wiener medicinische Zeitung*, 1887, xxxii, 596). He had seen four cases—three in multiparæ and one in a nullipara—which subsequently became malignant and required extirpation of the uterus. He describes it as beginning as a small hypertrophic development upon the mucous membrane, usually upon the anterior lip, which may be as large as a lentil or a chestnut. It may become eroded or ulcerated and bleed freely. Its structure is papillomatous, with new glandular formation, and at the border of the erosion there may be groups of epithelial cells in nests, as in epithelioma. It may develop into epithelioma, but perhaps not until years have elapsed. The rodent or corroding ulcer of the vaginal portion was described by John and Charles Clarke, and is also a rare form of ulceration. John Williams has described three cases (*Transactions of the Obstetrical Society of London*, 1885, p. 60), and a paper upon the same subject has more recently been contributed by Browicz (*Centbl. für Gynäkologie*, 1888, p. 94). This disease is quite suggestive of lupus, may continue for years, and may terminate in carcinoma. One of Williams's patients was under observation ten years, the second died from paralysis nine years after the discovery of the ulcer, and in the third the cervix and vagina were nearly destroyed by the ulcerative process, and the fatal issue was probably influenced thereby. Browicz found no traces of carcinoma in his investigations, nor did Williams in either of his cases, but the number is too small to be considered as an argument against the development of carcinoma with this

condition. The rodent ulcer is seen almost solely among the aged, with whom degenerative changes take place slowly. As this condition upon the exterior of the body may degenerate or develop into carcinoma, I see no reason for thinking that the same result may not occur upon the vaginal portion of the cervix uteri. For this condition, therefore, as well as for all other forms of ulceration which refuse to heal after treatment for a sufficient length of time with astringent and stimulating applications, amputation is indicated, not only for its diagnostic but also for its probable curative value.

I have referred to glandular disease of the vaginal portion as leading to uncertainty concerning the presence or absence of malignant disease, because nearly or quite all the subject of erosions and ulceration of the os uteri is referred by Ruge and Veit to the new formation of glandular tissue. Included also are the retention cysts and follicles of the vaginal portion as a part of the same process. Ruge and Veit see in this condition not only one which is very suspicious, but one which it is often impossible to differentiate from carcinoma. The carefulness with which their investigations were made and the closeness of their reasoning compel respect, though clinical experience may not always harmonize with their conclusions. I believe, however, that their investigations would amply justify the proposition which I have suggested—to perform amputation in all cases in which the diagnosis is doubtful. I have said that stimulating and astringent applications were sometimes indicated before resorting to amputation. There is a degree of uncertainty as to the result in such treatment. It is impossible to foretell the degree of tissue irritation which will be caused by contact with a powerful astringent or caustic. I have seen cases in which the application of powerful solutions of chloride of zinc seemed to stimulate a malignant growth to increased activity. Spanton recently reported (*British Gynecological Journal*, 1890, vi, 70) a case in which nitric acid was applied to a supposed syphilitic ulcer of the vaginal portion, the patient being at the same time subjected to constitutional treatment. The ulcer healed, but in six months another appeared upon the same situation, and examination of the excised tissue revealed its malignancy. In the discussion of Spanton's paper Inglis Parsons stated that many cases were on record (unfortunately, none were referred to) in which cancer had formed upon the site of syphilitic lesions. On the same occasion Fenwick reported a case in which there was a supposed syphilitic erosion of the vaginal portion. It disappeared in two weeks without treatment, but three months later there was a malignant growth of the cervix and vagina.

It may be asked why this operation is proposed rather than the high amputation of the cervix, which was so earnestly advocated by Schröder. The reply, which is a reiteration of what has already been said, is that this operation is proposed chiefly for diagnostic purposes; incidentally it will be curative in a certain proportion of cases.

Schröder believed that carcinoma of the vaginal portion usually remained limited to the cervix, and hence consistently and logically performed high amputation in such cases, while hysterectomy was reserved for those in which

the body or the supravaginal cervix were involved. (See Winter. *Zeitschrift für Geburtshülfe und Gynäkologie*, xxxii, 1, p. 196.)

There is probably a field for the supravaginal amputation, though I doubt if it is as extensive as is believed by Hofmeier, Winter, and others of Schröder's followers; but this is not entirely german to the question under discussion. The same may be said of an indication for amputation of the vaginal portion, which occasionally occurs in the coexistence of carcinoma with pregnancy. The supravaginal operation is manifestly inadmissible, while the other operation can usually be done without great danger to mother or child. Interesting cases of this character have been recorded by Ashton (*Maryland Medical Journal*, 1887, xviii, p. 77) and Godson (*Transactions of the Obstetrical Society of London*, 1884, xxv, p. 18). Concerning the method of performing the operation I have nothing new to offer. It is a simple operation, and I have usually performed it with curved scissors and a tenaculum or volsella. In cases in which the tissue is very dense a knife is preferable to scissors. The circumstances connected with each individual case will determine whether it is better to cauterize the wounded surface of the uterus, to allow it to granulate, or to cover it with the contiguous mucous membrane of the vagina.

159 EAST THIRTY-SEVENTH STREET.

**The Study of Cancer.**—"Professor Adamkiewicz, of Cracow, who has been making researches on the aetiology and treatment of cancer, which he thinks likely to lead to important practical results, recently applied to the Austrian Minister of Education for permission to pursue his investigations in a larger clinical field than he can command at Cracow. The minister has placed the material in the First Surgical Clinic of the Vienna General Hospital at his disposal for the purpose during the next winter semester."—*Boston Medical and Surgical Journal*.

**Glycerin for Burns.**—"According to Dr. Grigorescu, of Bucharest, glycerin is a perfect and lasting analgesic in the case of burns. Applied at once to the burned surface, it occasions at the instant of application a slight feeling of burning, followed by complete relief from pain. Where the wound is large it should be kept constantly moist with glycerin. By means of this application inflammation is almost entirely avoided, and sloughing takes place gradually, leaving a much less marked scar than is the case with ordinary dressings."—*Druggists' Circular and Chemical Gazette*.

**The Society of Medical Jurisprudence.**—At the next meeting, on Monday evening, the 14th inst., Dr. William A. Hammond, of Washington, is to read a paper on A New Substitute for Capital Punishment and Means for preventing the Propagation of Criminals.

**Honorary Degrees.**—The *Lancet* announces that the senate of the University of St. Andrew's has resolved to confer the honorary degree of LL. D. on Professor Michael Foster, M. D., of Cambridge, and Professor George McLeod, M. D., of Glasgow.

**The Medico-chirurgical College of Philadelphia.**—The chair of obstetrics has become vacant by the resignation of Dr. E. E. Montgomery, who will hereafter devote himself entirely to the chair of gynecology.

**The Annals of Surgery.**—It is announced that this journal is henceforth to be published in Philadelphia, by the University of Pennsylvania Press. It will still be edited by Dr. Lewis S. Pilcher, of Brooklyn.

**The St. Louis College of Physicians and Surgeons** will hold its annual commencement exercises on Monday, the 14th inst.

NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, MARCH 12, 1892.

THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE.

ON the general question of the advisability of extending governmental aid to medical education we do not feel called upon to express an opinion. We do feel at liberty, however, to say that, once the Government has entered upon an undertaking that is designed to further that purpose, it should not weaken its efforts. These remarks are called forth by a proposition now before Congress to reduce the annual appropriation for the Library of the Surgeon-General's Office from ten thousand dollars to five thousand.

The library has for many years been widely known as one of the leading medical libraries of the world, and its management has been in such competent hands that it has proved of material usefulness to the whole medical profession, as well as to the medical corps of the army. Primarily, of course, the object of the library, as well as that of the Army Medical Museum, is to strengthen the resources of the medical officers of the army. If incidentally it at the same time benefits the whole medical profession, it does it at no additional cost; and, since the medical corps of the army is recruited from physicians in civil life, it goes without saying that the higher we can make the standard of attainments among the profession at large, the better will be the quality of the material on which the army can draw for the care of its sick and wounded.

All this is well known to thoughtful and well-informed persons, and it is to be hoped that our national legislators need only have their attention drawn to these considerations to lead them to lay aside all thought of crippling so beneficent an institution as the library by reducing an appropriation that is already none too large. Surely, in view of the country's prosperity, no requirement of economy calls for such a course.

PROGRESSIVE UNILATERAL ATROPHY OF THE FACE.

This is a rare disease, beginning early in life and occurring more frequently among women than among men. An instance of this disorder was first recorded by Parry in 1825, but the singular abnormality only received attention after it had been described by Romberg thirty years later. The disease has followed acute rheumatism, erysipelas, and syphilis, and appeared in persons hereditarily predisposed to tuberculosis. In one very remarkable case the affection began after an attack of scarlet fever with diphtheria at the age of six, and an attack of typhoid fever many years after was followed by distinct atrophy of the other side. Gowers gives as a fact in the history of one case the existence of the same trouble in an aunt of the patient's. With the exception of deformity and impaired motility

of the month, the condition causes little or no inconvenience, and though the prognosis as regards cure is unfavorable, it does not shorten life.

The most striking symptom is the obvious deformity. In well-marked cases the diagnosis presents no difficulties. But when the atrophy is but slight, the affection may possibly be confounded with facial paralysis, progressive muscular atrophy affecting the facial muscles, unilateral hypertrophy of the face, congenital asymmetry of the face and head, and central lesions, such as tumors at the base of the brain involving the fifth nerve. The chief points in the diagnosis are the slow and insidious onset, the chronic and progressive course, and the unilateral character of the atrophy, that in the majority of cases is sharply limited to the area of distribution of the fifth nerve, together with the fact that the skin and subcutaneous fat are the tissues most affected. When the disease appears before the skeleton is fully developed, the bones also are involved. Even in cases of later manifestation the bones probably undergo some change. The tongue on the affected side is often atrophied. White patches of morphaea may appear in the skin, and are by some considered the earliest visible change. More frequently, however, when the disease comes under observation, the skin presents a mottled appearance, owing to yellow or brown pigmentary deposits. Sometimes there is the glossy condition characteristic of trophic nerve disturbance. Anidrosis of the diseased region is not uncommon. The hair on the affected side may change color, become thinner, or fall out in places. The pupils are equal. Subjective sensations—such as pain, tingling, and burning—occasionally exist, but cutaneous anaesthesia or hyperaesthesia is rarely present. The sight, hearing, and smell are normal. Alterations in the sense of taste are exceptional. The electrical reactions in typical unilateral atrophy of the face present no distinctive changes, although there is diminution in some cases.

The subject is considered at length in the latest fasciculus of Bramwell's *Atlas of Clinical Medicine*. Local injury to the face or head seems in certain instances to have been the exciting cause. Mr. Jonathan Hutchinson's view is that facial unilateral atrophy is "nothing more than the arrest of growth following fifth-nerve morphaea." Clinical facts support the theory that it is a nerve lesion involving the trophic nerve fibers or cells of the fifth nerve. There is also some evidence in favor of a central origin. Mendel's post-mortem examination in the case reported by Virchow, in which the skin and muscles of the upper extremity were also affected, revealed the fact that, notwithstanding the distinct wasting of the facial muscles as the result of a simple atrophy, the facial nerve was healthy. The fifth nerve was diseased in all its peripheral branches, especially the second, and was affected with an interstitial neuritis. There was no change in the motor and sensory ganglia, though the descending root of the nerve within the medulla oblongata was atrophied. During life the sensibility of the skin on the affected side had not been impaired. The radial nerve was the seat of a peripheral interstitial neuritis. The nerve cells in the anterior horn of the spinal cord, at

the level of the origin of the fifth cervical nerve, corresponding to the origin of the radial nerve, were decidedly less numerous on the affected than on the sound side.

Opinions may readily differ in regard to the relative importance of the central and peripheral lesions in this particular case. If the atrophy of the tongue that sometimes exists is due to a nerve lesion, Bramwell very justly observes that it must involve the multipolar cells of the hypoglossal nerve nucleus, or their peripheral prolongations, within the medulla or outside it. In this event, the present view of restricted fifth-nerve lesion as the sole pathological factor will be proved to be unsatisfactory. The nutrition of the muscles of the tongue may possibly be maintained and regulated by nerve cells other than the multipolar nerve cells of the hypoglossal nucleus. In researches on the minute anatomy of the hypoglossal and other nerves of the medulla, Alexander Bruce found groups of small round cells in close connection with the nuclei of the hypoglossal and some of the other motor nerves. These small round cells may have a trophic function. Involvement of any part of the hypoglossal nerve must be determined by future post-mortem observation.

Experimentally, unilateral atrophy of the face has been induced in a dog by Girard (*Revue méd. de la Suisse romande*, 1891), who divided within the skull the sensory root of the fifth nerve, with the following results: Progressive unilateral atrophy of the muscles of mastication and of the bones and tongue on the same side, together with thinning of the skin and asymmetry of the face. From this Girard concludes that the trophic fibers of the trifacial nerve are contained in its sensory root, and that the facial nerve plays no part whatever in progressive unilateral facial atrophy. He also calls attention to two distinct forms of this particular disease—namely, the typical form due to defective power of function of the trophic fibers of the trifacial nerve, and a facial pseudo-trophoneurosis consequent on atrophy induced by paralysis of muscles following motor-nerve disease. In other words, there is a partial unilateral atrophy following neuritis of the facial nerve. This is an interesting and just distinction.

Two very instructive examples of this disease are reported in the *Neurologisches Centralblatt* for 1891, of which one is recorded by Muratow. The patient first sought treatment for clonic spasms in the muscles of mastication on the right side. Afterward the spasms became tonic and bilateral. Atrophy of the right side of the face had preceded the convulsive movements, together with facial asymmetry and thinning of the lips and tongue on the affected side. There was no alteration in the electrical reaction. Antedating the facial atrophy by several years were spots of circumscribed scleroderma (morphaea) on the right side of the face and on the back, which were at first white and the seat of a tingling sensation. Subsequently the sclerosed patches thickened and became yellowish-brown. The second case, Jankan's, occurred in a patient twenty-two years old, hereditarily predisposed to tuberculosis and consequently to chronic inflammations. The condition of unilateral atrophy followed hypertrophic pharyngitis and ozæna. Two

years before the patient's coming under observation there had been white patches on the right side of the face, atrophy, and localized deposits of yellowish pigment. The hair on the affected side had fallen out in spots, and the bone conduction of sound differed materially from that of the healthy side, which would seem to indicate some change in the bones of the skull. The thyroid gland was increased in volume and consistence. The urine was high-colored, and contained an excess of chlorides, indican, and uric acid. The author of the paper states that all three branches of the trigeminus were involved.

In an Italian journal Borgherini gives an account of another interesting and unusual case, manifestly of peripheral origin, occurring in a peasant over sixty years old and coming on after incision of the lacrymal gland to relieve phlegmonous dacryocystitis. This incision was followed by pains and formication about the orbit, together with a sensation of numbness in the skin as far as the right ala of the nose. There were spasms of the muscles of the face and forehead on the right side, also unilateral atrophy and keratitis and subsequently opacity of the cornea. By degrees the disease advanced as far as the lower border of the temporal muscle, involving also the masseter, but remaining limited to the territory supplied by the fifth nerve. In time the pathological process involved certain parts of the left side of the face. The atrophied muscles gave no response to faradism. Direct galvanic excitability was absent in all the muscles supplied by branches of the trifacial nerve. There was the reaction of degeneration on the left side in the muscles of the lips and in the orbicularis palpebralis.

While treatment fails to effect a cure, it is not improbable, Bramwell thinks, that in cases where the process becomes arrested this happy circumstance is due in part to therapeutic measures. The indications are to arrest the atrophic process and to maintain and restore the nutrition of the affected region. All conditions that produce nerve exhaustion should as far as possible be avoided. Nervine tonics are the most valuable, such as arsenic, strychnine, iron, and quinine. Massage of the face should be tried, care being taken to avoid irritation of the skin. The systematic and diligent practice of voluntary movements for a regular stated time each day must be insisted upon. Both forms of the electric current, constant and faradaic, have been employed with apparent benefit. The experiment of resection of the various branches of the trifacial nerve, as far as accessible, is advocated by Dr. F. X. Dercum (*Journal of Mental and Nervous Disease*, February, 1892). The maximum benefit to be derived from interrupting the communication between the trophic center and the peripheral distribution can only be obtained by an early operation, one performed as soon as the ominous white patch that is often the initial change makes its appearance on the cheek. Should the experiment fail, its advocate maintains that little or no harm can result, anesthesia being the only unpleasant consequence, and to this patients readily adapt themselves. The do-nothing plan of treatment is highly reprehensible.

## MINOR PARAGRAPHS.

### STEAM AS AN AGENT IN CAUSING THE SPREAD OF DIPHTHERIA.

In a discussion on diphtheria, published in the *British Medical Journal* for September 19, 1891, Dr. Russell cited several instances in which steam had seemed to be an active factor in the propagation of the disease. Hot water and steam from a brewery were introduced into some old cesspools and evidently wakened into activity germs which, if undisturbed, would have remained dormant. An epidemic of diphtheria soon developed in the vicinity, and was not checked until the steam was turned into other channels, when it quickly ceased. If, as we now believe, the bacillus of diphtheria develops with special rapidity in the presence of warmth and moisture and absence of light, it is not unreasonable to suppose that the introduction of hot water or steam into cesspools or sewers may be a most dangerous procedure. The maintaining of a considerable degree of heat in sewers can certainly not be wise from a hygienic point of view. Yet this condition prevails quite largely in New York, where sewers and water pipes are in many places kept at a continuous high temperature by the close proximity of the pipes of the steam-heating companies. No more favorable medium for the culture of micro-organisms could be found than warm sewage. Given an imperfect trap and a vulnerable mucous membrane, and an attack of diphtheria is almost assured.

### DISEASE OF THE BRAIN FOLLOWING A SIMPLE NASAL OPERATION.

The *Journal of Laryngology, Rhinology, and Otology* gives an abstract of an account of an unfortunate accident described by Wagner in the *Münchener medicinische Wochenschrift*. The author performed a galvano-cauterization of the left turbinated body in a patient twenty years of age, on account of headache. There was no special pain and there was no bleeding. The next day the patient had a severe headache, and on the third day there was hæmorrhage from both nasal cavities. This was treated first with ice water, then by tamponing the anterior and posterior nares. In the evening the patient became feverish, and Cheyne Stokes respiration appeared. The tampons were removed, but the temperature did not fall and symptoms of a severe affection of the brain appeared. Seven days later death occurred. A post-mortem examination was not allowed. The author concludes that the bleeding could not have been the direct consequence of the operation, because it followed some days afterward, and because parts bled which had not been operated on. He believes that thrombosis of a sinus occurred, which disturbed the circulation in the nose. In some other published case operative treatment of the middle turbinated body was followed by meningial disease.

### LEPROPHOBIA IN PHILADELPHIA.

It is stated in the public press that the health officer of Philadelphia, having discovered that a leper had been employed as a cook in a hotel in that city, has recommended that the hotel be closed, the furniture disinfected, the house fumigated, and the proprietor arrested for maintaining a nuisance prejudicial to public health. We are glad to be able to state that the health officer is not a physician, and thus relieve the medical profession of the responsibility for such unscientific and uncalled-for measures. Philadelphia officialism seems to be afflicted with leprophobia, and at any time it might be expected

to declare quarantine against Louisiana because there are a few cases of leprosy in that State.

#### THE INFLUENCE OF THE NERVOUS SYSTEM UPON INFECTION.

OBSERVATIONS by Féré upon this subject are noted in the *Mercure médical* for February 10, 1892. In an earlier communication he had made known the fact that vaccine virus proved more efficacious in paralytics upon the affected than upon the sound side. This is also true in cases of infantile paralysis. Vaccination during the stupor following epilepsy was performed upon all epileptic patients without result, with one exception only.

#### THE DECADENCE OF THE GRADUATION THESIS.

THE *Progrès médical* and the *Gazette des hôpitaux* are favoring the discontinuance of the custom of requiring a graduation thesis from candidates for the Paris medical degree. There is much to be said for and against the requirement. We are under the impression that it was done away with several years ago by the New York College of Physicians and Surgeons, and the action of the school does not seem to have worked to anybody's disadvantage.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending March 8, 1892:

DISEASES.	Week ending Mar. 1.		Week ending Mar. 8.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	32	4	20	3
Typhoid fever.....	12	13	8	4
Scarlet fever.....	241	35	219	38
Cerebro-spinal meningitis.....	1	2	2	4
Measles.....	339	18	337	21
Diphtheria.....	132	48	119	43
Small-pox.....	4	3	6	1
Erysipelas.....	1	0	0	0
Varicella.....	17	0	12	0
Pertussis.....	1	0	1	0
Mumps.....	0	0	2	0

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 28 to March 5, 1892:*

KEAN, JEFFERSON R., Captain and Assistant Surgeon, is relieved from duty at Fort Robinson, Nebraska, and ordered to St. Francis Barracks, Missouri, for duty, not later than March 25, 1892, relieving DAVID L. HUNTINGTON, Major and Surgeon. Major Huntington, upon being relieved by Captain Kean, will proceed to New York city for duty in connection with the Army Medical Board.

WYETH, MARLBOROUGH C., Captain and Assistant Surgeon, is relieved from further duty at Fort McIntosh, Texas, and ordered to Fort Supply, Indian Territory, upon the expiration of his present sick leave of absence.

TAYLOR, MARCUS E., Captain and Assistant Surgeon. Granted leave of absence for six months on surgeon's certificate of disability.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending March 5, 1892:*

BRUSH, GEORGE R., Medical Inspector. Ordered to the Navy Yard, Brooklyn, N. Y.

KERSHNER, EDWARD, Medical Inspector. Detached from the Navy Yard, New York, and ordered to the U. S. Steamer San Francisco.

CLARK, J. H., Medical Inspector. Detached from the U. S. Steamer San Francisco and ordered home.

GIBON, A. L., Medical Director. Detached from the Naval Hospital

and assigned to special duty at New York, attending officers of the Navy and Marine Corps.

SCOFIELD, W. K., Medical Director. Detached from special duty at New York, attending officers of the Navy and Marine Corps, and to wait orders.

BOGERT, E. S., Medical Director. Detached from the Medical Examining Board and ordered to the Naval Hospital, Brooklyn, New York.

DE VALIN, C. M., Assistant Surgeon. Ordered to the Naval Hospital, Norfolk, Va.

#### Society Meetings for the Coming Week:

MONDAY, *March 14th*: New York Academy of Medicine (Section in General Surgery); New York Ophthalmological Society (private); New York Medico-historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Lenox Medical and Surgical Society (New York—private); Society of Medical Jurisprudence (New York); Boston Society for Medical Improvement; Gynæcological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

TUESDAY, *March 15th*: New York Academy of Medicine (Section in General Medicine); New York Obstetrical Society (private); Medical Society of the County of Kings, N. Y.; Ogdensburgh (N. Y.) Medical Association; Baltimore Academy of Medicine.

WEDNESDAY, *March 16th*: New York Academy of Medicine (Section in Public Health and Hygiene); Northwestern Medical and Surgical Society of New York (private); Harlem Medical Association of the City of New York; Medico legal Society (New York); Medical Society of the County of Allegany (quarterly), N. Y.; New Jersey Academy of Medicine (Newark).

THURSDAY, *March 17th*: New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private).

FRIDAY, *March 18th*: New York Academy of Medicine (Section in Orthopædic Surgery); Baltimore Clinical Society; Chicago Gynæcological Society.

SATURDAY, *March 19th*: Clinical Society of the New York Post-graduate Medical School and Hospital.

#### Answers to Correspondents

No. 374.—The following comparative analysis is given in Dr. Rotch's article in Keating's *Cyclopædia of Diseases of Children*:

	Human milk.	Cow's milk.

## Letters to the Editor.

#### INTUBATION IN TUBERCULAR LARYNGITIS.

COLUMBUS, OHIO, *February 29, 1892.*

To the Editor of the *New York Medical Journal*:

SIR: Apropos of Dr. F. E. Hopkins's report of a case of intubation in tubercular laryngitis, in your last issue, I desire to state that in the *Medical Record* of March 8, 1890, I reported a case of intubation for the relief of dyspnoea in tubercular laryngitis. Although, according to Dr. Hopkins's article, I presume I was the first to adopt this method of securing relief, I am merely a general practitioner, not a specialist, and hence did not imagine that I had done anything very wonderful.

J. F. BALDWIN, M.D.

## Proceedings of Societies.

### NEW YORK NEUROLOGICAL SOCIETY.

*Meeting of February 2, 1892.*

The President, Dr. LANDON CARTER GRAY, in the Chair.

**Eachymeningitis and Myelitis.**—Dr. MARY PUTNAM JACOBI read an account of a case of this condition, which had at first been supposed to be due to Pott's disease, but in which a solid tumor had developed against the spine during the last weeks of life, and been diagnosed as sarcoma.

**The Surgical Treatment of Epilepsy.**—Dr. JOSEPH PRICE, of Philadelphia, read a paper in which epilepsy was defined as an apyretic nervous affection characterized by seizures of loss of consciousness with tonic or clonic convulsions. Its history, from a therapeutic standpoint, was one that had taxed the efforts of supreme superstition and defied the resources of scientific medication. Its treatment had been one of trial and disappointment, for it still remained one of the greatest opprobria of medicine. Its attacks were visited upon both sexes, hysteropilepsy for the most part being confined to females. Women were attacked when a marriageable age was reached. Debauchery had frequently led to it. Young widows were prone to attacks, and its origin outside of physical causes might be traced to amorous songs and certain stimulants, such as chocolate and coffee. For its cure various suggestions had been made, among others that of resorting to venery. It had, however, been abundantly proved that excessive lust had produced epilepsy, and was, no doubt, yet to be recognized as a great factor in its causation. That it was transmissible did not admit of dispute any more than that it was caused by traumatism. Operative interference in the traumatic cases, for the removal of the cause, was logical and often successful. The operation of clitoridectomy had brought Baker Brown into disrepute, and yet we had to-day no less a person than Lawson Tait boldly expressing the opinion that there was doubtless a place for the operation. The belief that a moral element must be reached in addition to the physical interference was no doubt justified by the facts. One table that the author had consulted gave as high as 73.7 per cent. of patients cured of masturbation by clitoridectomy. This surely made it not presumptive to favor its recognition. Epilepsy in women appeared to be more fatal than in men. The acquired epileptic habit was more fatal than the congenital. In the congenital form it was twice as fatal, and in the acquired form three to four times as fatal, in women as in men. As to the hereditary nature of the disease, it was sufficiently evident to require that marriage should be discouraged among epileptics. The history of eunuchism as a preventive of epileptic propagation, and also the edicts forbidding the marriage of epileptics, were of interest to the student of law as well as to the theologian and the physician. In the treatment of epilepsy proper there was no doubt that surgery must form an important factor, whether in traumatic cases or for the removal of reflex causes. In entering upon the consideration of the removal of the uterine appendages in women for the cure of epilepsy it was unnecessary to take up in detail the history of castration as practiced upon the male for the same purpose. Suffice it to say that the history of this operation, both from a priestly standpoint and from a carnal or musical standpoint, was often instructive and oftener horrifying. The mortality was often simply terrible, while the practice of mutilating children to preserve their voices for song marked an era of refined religious cruelty scarcely conceivable. So far as the surgery of the disease was concerned, in a general way the operation had the best of the argument. Out of sev-

enty-one cases treated medically, and out of a second series of seventy one treated surgically, statistics showed that by the surgical treatment all were at least benefited, while in the medical series a great proportion showed no effect at all from treatment, and in others the conditions were aggravated. In a general surgical way, then, if the operation was beneficial when the trouble could be directly traced to the ovaries or their diseases, logical deduction would seem to indicate that beneficial results might at least be hoped for. So far as unsexing an epileptic was concerned, the author did not understand how or why there was reason to feel compunction at such a suggestion. He could hardly question the protective value to society, not only of forbidding epileptics to marry, but of rendering them unable to procreate. Wise legislation would of course be needed to prevent abuse, but the essential right of society to protect itself ought not to be questioned. Aside from the actually demonstrable disease, what was to be done in the presence of epilepsy? In the case of an unmarried woman in whom every menstrual period, from the initiation of puberty to the time that she came under the physician's care, was marked by an epileptic seizure, who at other times was entirely free from attacks and showed no tendency to fall into them, who recovered as soon as the period was over, and who had no other demonstrable disease or probable cause of seizures than her monthly irritation, there was little doubt that an operation was justifiable. Unless we could thus pin down the seizures to definite time and cause, the author held that it was wrong to burden surgery with an operation that could not fail to detract from its good name, while it did no possible good to the individual. If ovarian disease was found to be the cause of the epileptic seizures, it was of no use to do a partial removal and expect relief or cure. The effect obtained might be due to either one of two causes: first to the removal of an irritable or diseased organ whose presence stirred up the reflexes into a commotion, or to the excitation by the operation of a different epileptigenous zone. Charcot had laid down as a principle that irritation of one epileptigenous zone might be relieved by irritation of or pressure upon another. Assuming it as a fact that the disease was often a reflex manifestation of a local trouble, it followed that in those cases in which deposits were found as a result of a systemic affection resort should be had to the recognized remedies, and the chances for effecting a cure were equal to those of cases where operative interference was resorted to.

Dr. C. A. HERTER thought it unfortunate that no autopsy had been made in the case reported by Dr. Jacobi, as the diagnosis seemed open to a good deal of speculation. There was apparently no justification for the assumption that two lesions existed, and a single one would explain the symptoms. This lesion might have been one of sarcoma or of tubercular disease, and it would be difficult to determine which.

Dr. W. H. THOMSON disagreed with the last speaker. The chief point of interest was in the fact that there might have been two distinct lesions in the cord, presenting in their symptoms the contrast in the nature of the lesions. It was well known that in the case of tumors pressing upon the cord there was present as a symptom local pain, especially in movement of the parts. Transverse myelitis would present this kind of pain, and, unless it was accompanied by distinct meningitis, there would be no irritation of the nerve roots. Therefore, according to the description, there might have been two conditions of the cord occurring in the same patient. The symptoms developing afterward in the legs were the sequelae of transverse myelitis. Finally, the effect of the presence of a tumor invading and spreading into the tissues was simply pressure at that point.

Dr. B. SACNS doubted if in the majority of cases there was

myelitis associated with the presence of a tumor, though in a tuberculous case this sometimes occurred. Tubercular myelitis was distinguished by being more destructive to the substance of the cord than other forms.

Dr. JACOBI said that the reason for supposing that there was a second lesion differing from the original one was the persistence of the epigastric reflexes. It was presumed that there was a tumor of the cord beginning in the first dorsal vertebra, causing pachymeningitis at that point followed by myelitis.

Dr. H. J. BOLDT, speaking on the subject of Dr. Price's paper, thought that some nervous diseases might be due to menstrual disorders, but they were not numerous. The removal of the uterine annexa was one of the gravest operations in surgery, both in its medical and in its medico-legal aspects. It was most important to select the cases. When absolute pathological conditions were present and treatment had been carried on unsuccessfully by all the methods known to the profession, and when a gross lesion could be discovered to be present in the annexa, the operation was perhaps justifiable and good results might accrue. If the epileptic attacks were restricted to the menstrual period, and it was concluded that the prime cause lay in the annexa, the operation might be resorted to, but little else but bad results were to be expected.

Dr. G. M. HAMMOND thought that two points should be borne in mind—the establishment of the epileptic habit, and the influence of pathological conditions of the uterus and ovaries in producing epilepsy. The fact that operations performed on the brain for the relief of epilepsy when there existed a well-defined lesion were not in the majority of cases followed by cure of the seizures was well known now. The habit persisted, and many of the patients so operated upon had been reported cured too soon. The condition was, in fact, only abated or rendered dormant for a more or less limited period. As to the influence of abnormalities of the genital apparatus in the production of epilepsy, it seemed to the speaker that those of the uterus were more potent than those of the ovaries. Lacerations, malpositions, and inflammations of the uterus were more likely to cause epileptic seizures than irritation of the ovaries. At a time when gynecologists were removing ovaries by the bushel, the speaker had sought to inform himself of some of the results by writing to a number of asylums. The questions put had been as to the cases of melancholia in which operation had been done. He had received a stock of reports. The consensus of opinion was to the effect that epilepsy and insanity had not been relieved by removal of the ovaries. As to the effect of oophorectomy in producing insanity, he had seen four or five cases of epilepsy and hystero-epilepsy come on in a few days after it had been performed. Others had met with the same experience. While he had seen some subjects of insanity and melancholia recover after relief from uterine irritation, he had never seen such result follow oophorectomy.

Dr. A. H. BUCKMASTER said it was hardly fair to call epilepsy a disease. It was a collection of symptoms which had no anatomical basis. It was influenced by irritation of all kinds, and naturally those produced in the reproductive organs would be of the most marked character, though observers were not agreed upon the exact rôle that these organs played in this respect. The previous speaker was probably correct in assuming that more irritation could arise from injuries of the uterus than from lesions in the Fallopian tubes or ovaries. The evidence was so strong that no good was accomplished by oophorectomy in the conditions under consideration that it was to be condemned.

Dr. W. M. POLK said his experience of the results of operations for the cure of hystero-epilepsy was limited to three cases, and was not such as to embolden him to continue to operate. Two of the patients had become insane, and the third one was

in a distressing condition of nervous irritability. Epilepsy was still really a fruitful field for investigation. It must be remembered that eighty per cent. of women were stated to be hysterical. A large amount of epilepsy was known to be due to peripheral irritation, and there was no reason why the ovaries should not set up some of this. If they did this, they should be taken out.

Dr. SACHS had seen a number of cases in which the operation had been done, and with no effect upon the epilepsy. It was a mistake to remove ovaries because the patient had epilepsy at the menstrual period. If it could be proved that the person had no congenital epilepsy, that the first attack had come on with menstruation, and that seizures had occurred constantly since, but only at the menstrual period, there might be some fair reason to remove some of the sexual organs. Because a woman was an epileptic and had sensitive organs which could be removed was a ridiculous argument in favor of their removal.

Dr. L. WEBER did not hold the view that the irritation following laceration of the uterus was a cause of epilepsy. In a large experience of twenty-eight years he had never seen more than two cases in which the epileptic condition had been thus induced, unless there was a history of hysterical or epileptoid taint before the age of puberty. He believed that true epilepsy acquired from lesions of the genital organs was a rare condition. He would only give his consent to operative interference on very narrow grounds and where there was a fair hope that by the removal of the ovary the condition could be cured.

Dr. BUCKMASTER explained that he had not meant that injuries to the uterus following parturition were active in producing epilepsy, but that of all lesions to the reproductive organs these were most likely to act as irritants, and were therefore quite likely to result in the nervous condition under discussion.

The PRESIDENT said that all neurologists were agreed that what was called the epileptic state was nothing more than a symptom indicating intracranial disturbance, spinal or peripheral nerve irritation, or inflammation of the visceral nerves. The most frequent source of the symptoms lay in intracranial disorders. Spinal epilepsy was rare, as was also that arising from peripheral irritation. How important a part the abdominal nervous system played was not quite known. But the most uncertain of all was the influence of the female generative organs in producing the epileptic symptoms. At any rate, there was not a single reputable record of the cure of epilepsy; not one that would stand the test of examination. To report relief for a few months or even a few years was to report nothing, and this was all that had been done. Almost every therapeutic or surgical measure had done good, but there was nothing more in the way of cure reported by modern effort than could be found chronicled by Esquirol in 1828.

Dr. PRICE reiterated his opinion that permanent benefit was possible in properly selected cases.

## NEW YORK ACADEMY OF MEDICINE.

SECTION IN GENERAL SURGERY.

Meeting of February 8, 1892.

Dr. JOSEPH D. BRYANT in the Chair.

**A Cutting Operation for the Relief of an Old Dislocation of the Inferior Maxilla.**—Dr. R. H. M. DAWBARN presented a patient who had suffered a long time with dislocation of the inferior maxilla, the mouth being permanently open. The patient had had several attacks which suggested tetanus, and many attempts on the part of skillful surgeons to reduce the dislocation had failed. As a last resort, the speaker had made incisions almost dividing both masseter muscles, enabling him

to reach the displaced bone and pry it back into place. The result had been permanent and satisfactory. In another case the speaker had been able to effect reduction after nearly dividing only one of the masseter muscles.

The CHAIRMAN thought that dislocations of the inferior maxilla must be preceded by relaxation of the muscular or ligamentous structures. In experiments upon animals it had been shown that dislocation could not be caused by spasmodic action of the muscles alone.

The further discussion of the question elicited several cases of the same character, due to a variety of causes, such as vomiting, talking, laughing, gaping, also the direct application of severe force, as that of a blow from the clinched fist.

**Primary Amputation, Consecutive Amputation, and Resection in Traumatism of the Extremities.**—Dr. T. H. MANLEY read a paper with this title. He believed that primary amputation should never be resorted to in civil life unless the vitality of all the tissues had been destroyed. In such cases amputation should not be delayed. In children, even though the injury was severe, amputation should be delayed as long as possible, and a resection should be preferred to amputation if practicable. In consecutive amputation after injury one could proceed along precise lines. The flaps should be as long as possible, should contain as much muscular tissue as practicable, and should be so approximated that the resulting scar would not be impinged upon by the end of the bone. During the operation he objected to the use of antiseptics about the bone. However unirritating they might be to the soft parts, he believed they often produced injury to the bone. If drainage-tubes were required they should be used for the shortest possible time. An abundance of soft gauze dressings was indicated in all cases. In cases of compound comminuted fracture of the thigh amputation would frequently be necessary for the reason that the femur seemed to tolerate such injuries less readily than the other long bones. Another reason for avoiding amputations in children, when possible, was that they bore the shock and loss of blood of such operations badly. In injuries of the hands and feet the successes of osteoplasty encouraged delay. Ollier had demonstrated the great reparative force of the periosteum; hence, though the bone was destroyed, if the periosteum was preserved the bone might be renewed. If the bone was shattered and separated from the periosteum, it (the bone) should be removed. The speaker was not in favor of the insertion or introduction of wedges of decalcified bone. In general it would be well to save as much tissue as possible in doing amputations, and to avoid opening joints when this could be done. If sublimate or other antiseptic solutions were used in the course of an operation, their use should be followed by abundant irrigation with plain hot water.

Dr. DAWBARN thought that the name of Macewen was quite as worthy of mention as that of Ollier in connection with the subject of saving bony structures. With reference to heteroplasty, he was in favor of the introduction of Neuber's decalcified bone wedges into the gaps between bone fragments.

Dr. R. H. SAYRE approved of the policy of waiting before amputation as a general principle, since reparative processes were often very vigorous.

Dr. F. KAMMERER thought the same rules should apply for adults as for children in the matter of primary amputation. It had not been his experience that the use of antiseptics upon osseous tissue was deleterious.

Dr. W. R. TOWNSEND thought that the conservative principle in the matter of saving tissue at the time of an amputation might be carried too far. If an amputation was imperative, one of the most important considerations was to obtain such a stump as would furnish a good base for an artificial limb.

The CHAIRMAN agreed to the statement that as much tissue as possible should be saved in performing an amputation, but it was equally desirable that only so much should be saved as would be of practical utility.

Dr. MANLEY was aware that Macewen attached comparatively little value to the periosteum as a means of repair. But, if he was right, all the teachings of physiology must be wrong. With regard to the value of decalcified bone for ossific centers, the speaker thought it had none. He had never seen a case of successful bone grafting.

**Senn's Hydrogen-gas Test.**—Dr. DAWBARN believed there were many objections to Senn's hydrogen-gas test for the determination of wounds of the intestine. Although he had never had an opportunity to try it upon the living subject, he had tried it twenty-two times upon the cadaver. The gas was stored in a large rubber bag and was pumped from the bag into the bowel by means of a Davidson's syringe. The result had been very great distention of the bowel, which in the living subject would be harmful. In all but two of the cases the hydrogen had found its way from the bullet wound which had been made in the intestine to the tube that was placed in an opening in the abdominal wall, and its presence had been ascertained by combustion when a flame was applied to the tube.

If a bullet wound, or other intestinal wound in which the test was applied, was clogged with feces, or if the lumen of the bowel was obstructed by fecal masses, the test would be unavailing. It was a well-known fact that not all bullet wounds of the intestine required treatment by abdominal section, for leakage from a wound might not take place if the wound was closely pressed upon by a coil or coils of uninjured intestine. On the other hand, the pressure of the hydrogen might force fecal matter out of a wound and into the peritoneal cavity and be followed almost inevitably by a fatal result unless an abdominal section was made. In those wounds of the intestine which occurred below the navel, abdominal section should be promptly performed and the hydrogen test would be unnecessary. On two occasions the application of the flame to the tube from which the hydrogen emerged had been followed by an explosion of the gas within the abdomen. If the conditions were ever such that a similar explosion should take place in the abdomen of a living person the result would probably be disastrous.

---

## Book Notices.

*The Microscope and Histology*; for the Use of Laboratory Students in the Anatomical Department of Cornell University. By SIMON HENRY GAGE, Associate Professor of Physiology. Third Edition, entirely rewritten. Part I. The Microscope and Microscopical Methods. Illustrated. Ithaca, N. Y., 1891. Pp. 96.

This volume deals particularly with homogeneous immersion objectives, the substage illuminator, the camera lucida, the microspectroscope, and the micropolariscope.

The author deserves credit for expounding his subject in a very readable form. No one will fail to detect easily that the work is the result of long experience in practical laboratory work, or that many obscure points in microscopic technique are skillfully explained.

Though the readers of the book are supposed to be familiar with the principles of optics, the author takes particular pains in impressing upon the student's mind the fact of the importance

of knowing the working of the optic systems and of their being explained.

The section on slides and cover-glasses and on mounting, labeling, and staining microscopical preparations will be found of assistance. The value of the book lies greatly in the fact that it gives the most recent methods of microscopy as found in the leading current literature.

#### BOOKS, ETC., RECEIVED.

A Case of Congenital Malformation of the Heart. Atresia of the Pulmonary Artery, with Persistence of the Foetal Circulation. By William T. Howard, Jr., M. D., Baltimore. [Reprinted from the *Archives of Pediatrics*.]

Humau Monstrosities. By Barton Cooke Hirst, M. D., Professor of Obstetrics in the University of Pennsylvania, and George A. Piersol, M. D., Professor of Histology and Embryology in the University of Pennsylvania. Part II. Illustrated with Thirteen Photographic Reproductions and Twenty-five Woodcuts. Philadelphia: Lea Brothers & Co., 1892. Pp. 112.

The Aetiology, Pathology, and Treatment of Diseases of the Hip Joint. By Robert W. Lovett, M. D., Out-patient Surgeon to the Boston City Hospital, etc. Boston: Damrell and Upham, 1892. Pp. 9 to 220. [Fiske Prize Fund Dissertation, No. xlii.]

The Human Figure: its Beauties and Defects. By Ernst Brücke, Emeritus Professor of Physiology in the University of Vienna, etc. With a Preface by William Anderson, Professor of Anatomy to the Royal Academy of Arts, London, etc. Authorized Translation, revised by the Author. With Twenty-nine Illustrations by Hermann Paar. London: H. Grevel & Co., 1891. B. Westermann & Co., New York.

Coca and Cocaine: their History, Medical and Economic Uses, and Medicinal Preparations. By William Martindale, F. C. S., etc. Second Edition. London: H. K. Lewis, 1892. Pp. viii to 76.

Impure Air, and Ventilation of Private Dwellings. (The Orton Prize Essay.) By Howard Van Rensselaer, M. D., Albany, N. Y. [Reprinted from the *Transactions of the New York State Medical Association*.]

Abscess of the Antrum, with Cases and Treatment. By I. P. Wilson, D. D. S., Burlington, Iowa.

Empiricism; Rational Practice; Practice under Guidance of Law. A Lecture to Medical Students. By Charles S. Mack, M. D., Ann Arbor, Mich. [Reprinted from the *North American Journal of Homoeopathy*.]

Tuberculin. The Value and Limitation of its Use in Consumption. By Charles Dennison, A. M., M. D., Denver, Col. [Reprinted from the *Transactions of the Colorado State Medical Society*.]

Rheumatism and its Treatment by Turkish Baths. By Charles H. Sheppard, M. D., Brooklyn.

To what Extent is the Diagnosis of Pregnancy possible in the Early Months? By Charles Jewett, A. M., M. D., Brooklyn. [Reprinted from the *Brooklyn Medical Journal*.]

An Account of the Influenza as it appeared in Philadelphia in the Winters of 1889-'90 and of 1891-'92. By J. Howe Adams, M. D. Philadelphia. [Reprinted from the *University Medical Magazine*.]

Trendelenburg's Posture in Gynecology. By Florian Krug, M. D., New York. [Reprinted from the *Transactions of the Association of American Obstetricians and Gynecologists*.]

Total Extirpation versus leaving a Stump in Operation for Uterine Fibro-myomata. By Florian Krug, M. D., New York. [Reprinted from the *New York Journal of Gynecology and Obstetrics*.]

Méthodes pour préparer de l'eau aseptique. Par le docteur J. F. Heymans. [Extrait des *Annales de la Société de médecine de Gand*.]

Annual Report of the Hospital of the New York Medical College and Hospital for Women.

The Demilt Dispensary, in the City of New York. Forty-first Annual Report, for the Year 1891.

First Annual Report of the State Board of Medical Examiners of New Jersey. 1891.

Transactions of the Detroit Medical and Library Association. 1891.

## Miscellany.

**Removal of the Uterine Appendages.**—The *Medical Record* for March 5th contains the following editorial article:

The *University Medical Magazine* of December, 1891, contains articles on the subject of the remote effects of the removal of the uterine appendages by Dr. Wharton Sinkler and Dr. Charles Carroll Lee. These articles are written in a judicial spirit, and present very fairly the opinions which medical men may and should hold at the present time regarding the matter in question.

Dr. Sinkler first shows what the ordinary phenomena are that follow removal of the ovaries. These phenomena, as has long been known, resemble in many respects the changes of the climacteric. They consist of flushings and sweatings, which are very common, appear early, and last with lessening intensity for two or three years. Disturbance of the heart's action, including rapid heart beat, is frequent; numbness and various parasthesiæ also appear. Patients may gain some flesh, but they rarely get fat, contrary to a common belief. They do not necessarily have wasting of the mammae, nor is there ever a change in voice or growth of coarse hair. The sexual appetite is not much changed for two or three years, but eventually tends to become lessened and abolished. Nervousness, irritability, and mental depression appear to be common, especially in women originally of a neurotic temperament. Insanity occurs undoubtedly in a certain percentage of cases, variously estimated at five or ten.

As to the effect of the removal of the appendages upon neuroses and psychoses, the consensus of opinion seems to be very decidedly to the effect that good is rarely accomplished and harm often done.

Very little, if any, trustworthy evidence is given to show that oophorectomy is useful in insanity, although in the periodic menstrual form some successes are reported. As periodic insanities are of the psycho-degenerative class, one must always expect a recurrence of the disease eventually. There is much evidence to show that, at least in neurotic persons, oophorectomy tends to produce a condition of mental depression amounting often to melancholia.

In true epilepsy, even of a menstrual type, the operation is useless. In hystero-epilepsy, which many gynæcologists seem to think is a form of epilepsy and not a form of hysteria, the removal of the ovaries is not a legitimate procedure. In certain forms of neurasthenia and hysteria minor, associated with decided pelvic trouble, the operation sometimes does good, but the results are slow, and the operation should not be attempted until every other measure has been carefully tried.

Dr. Lee's paper is a most candid and scientific presentation of the results of his own work. In the main his conclusions agree with that of others; but he does not find that removal of the ovaries produces the melancholic condition which has been observed by some.

The conclusions of Dr. Sinkler, which embody the main points given above, may be inserted here:

"The remote effects of removal of the ovaries and tubes upon the general health are, as a rule, to improve nutrition and to better the strength, especially if the operation has been done for diseased ovaries or pus tubes.

"That excessive gain of flesh is rare, and that change of voice,

growth of hair upon the face, and loss of feminine characteristics do not occur.

"That the sexual appetite in women is seldom changed by castration within two or three years after the operation, but after several years it becomes lessened.

"That it is often the case that after this operation patients are more nervous than formerly, and mental disturbances of various forms, insanity, and epilepsy, not infrequently follow it.

"That the influence of the operation is sometimes good upon insanity and epilepsy which are associated with severe dysmenorrhœa or occur periodically at the menstrual epochs; but when the insanity is constant, although it may be aggravated at the monthly periods, removal of the appendages is of no benefit. Hystero-epilepsy is seldom permanently cured by the operation. Prolonged after-treatment is generally necessary to relieve such cases.

"Local pain is often not relieved by the operation.

"Certain cases of neurasthenia which are associated with dysmenorrhœa, or with structural changes of the ovaries, are cured by the operation; nevertheless, no such case should be subjected to the operation without beforehand having the benefit of prolonged and patient treatment. It is unjustifiable to remove the ovaries and tubes in cases of neurasthenia, hysteria, etc., when these organs are healthy."

We trust that the general practitioner and ambitious gynæcologists will both consider carefully the foregoing conclusions. They undoubtedly embody the experience of the profession, gained—at what a cost—during the past ten years.

**The Baby Students' Relief Bill.**—Several of the more influential newspapers have come to the aid of the medical profession in its opposition to Assembly bill No. 513, and not all of them are published in the metropolitan district. We are glad to see such an article as the following, from the *Syracuse Daily Journal*:

For many years the better part of the medical profession have striven to elevate the standard of medical education. At county, State, and national associations addresses have been delivered and resolutions passed urging medical colleges not only to adopt a better system of instruction and longer courses of lectures, but, by frequent and thorough examinations, to ascertain the fitness of their students for advancement and graduation. The majority of the schools have given little heed to these addresses and resolutions. They did not adopt a graded course extending through at least three years. They have not required each student to pass numerous oral and written examinations. They have not turned from the even tenor of their ancient way—faulty, unnatural, and jumbled though it concededly has been. In most of the schools the examinations have been so infrequent and superficial as to be of little if any practical value; so that, of the horde of graduates annually turned out upon a confiding community, the fitness of the majority has been complacently surmised rather than rigidly ascertained. Indeed, we understand that in some colleges the candidate for medical honors has been subjected to but a single and brief compulsory examination by each of the seven or more eminent professors throughout his entire two identical courses of six months each. It is evident that while many bright students, in spite of the faulty system, did derive great benefit from the admirable lectures and clinical advantages and voluntary attendance at quiz classes, the one only required examination—and that at the close of the students' course—could have furnished little guarantee to the public that the graduate possessed adequate qualifications.

Failing to accomplish needed reforms and secure protection to community through the action of the colossal rival medical schools, the profession at last applied to the Legislature. After long-continued efforts, partial success was achieved. Laws were enacted requiring each person proposing to enter a medical college to satisfy a State Board of Examiners that he possessed at least a fair acquaintance with the elementary branches of an English education. They also required him to attend three courses of lectures, and then, after obtaining his diploma from the college, to have his fitness to receive a license to practice ascertained by a carefully selected, independent State board. These laws were to take effect on the first of September, 1890, but were not to be applicable to those students who matriculated in 1889 or prior to that time.

The lazy and unworthy person who entered a medical college in 1890 had a full knowledge of the requirements. He received due notice that he could no longer neglect attendance on lectures and clinics and quizzes and feel assured that his easily obtained diploma would give him license to practice. He knew that, unless the wholesome law could be repealed or its action postponed till the next year's crop of candidates should be ripened, his ambition to gain an undeserved access to the bedside of human suffering would be checked by the ordeal through which all bright and worthy students willingly and successfully pass. So he summoned to his aid a great number of the dubious and timorous and incapable (who knew well enough that they would certainly pass the college examination and receive diplomas), and petitioned the Legislature to exempt him and them from this terrible examination of the State board, but righteously to subject all who should come after them, and all doctors coming from other States, to its searching and beneficent exactions. Thoughtlessly the Senate complied with the cowardly and unmanly petition, and passed the bill known as Assembly bill No. 513. There is no good reason why the qualifications of every medical graduate of 1893 to practice should not be determined by the Board of State Examiners.

In the interest of humanity the passage of this bill, No. 513, whose title should be: *An act to promote the admission of incompetent persons to the medical profession*, should not be possible. The Syracuse medical association unanimously protests against its passage. The Faculty of the College of Medicine of Syracuse University unanimously oppose its passage. And, to the high honor of their class, not one of the students of the college who would be affected by it has petitioned to have it passed.

It is but justice to the Syracuse college to state that it did not wait for compulsory legislation. We are informed that from its organization, twenty years ago, it has required an entrance examination—increasing beyond the State requirements in its salutary exactions. It has had a graded course extending through three years of eight months each instead of the customary two years' course of six months. Every graduate has been subjected to more than three hundred oral or written examinations before receiving his diploma; and he is willing and ready to go before the State board for its examination.

The public should join the medical profession in demanding that the safeguards against dangerous medical incompetency shall not be disturbed.

**Chronic Endometritis.**—At a recent meeting of the Philadelphia County Medical Society, Dr. J. M. Baldy read a paper in which he said that of late years it had become the habit of gynæcologists to consider almost all endometrial diseases as symptomatic, and not as independent lesions. It was certainly true that many pelvic diseases were accompanied by an unhealthy condition of the endometrium; especially in pelvic inflammatory disorders the lining membrane of the uterus was so frequently affected as to have given rise to the supposition that either it was caused by the pelvic disease or rarely occurred independently of it. In fact, such assertions were frequently made in print and before societies. The temptation was strong to accept this theory, which appeared at first blush to be so plausible, but which was nevertheless most fallacious. His daily experience was teaching him that endometritis as an independent disease was quite a common disorder, and was at the bottom of many of the discomforts suffered by women. The causes giving rise to this disease were much the same as those that originated colpitis, and particularly salpingitis—specific infection and post-puerperal sepsis being the most prolific, and giving rise to the bulk of the cases. Oftentimes the beginning of the trouble could easily be traced to a childbirth or to an abortion. The woman had had a slow getting up, and would give the history of some fever, or she had regained her usual health very slowly, possibly not at all; she would have complained of a vaginal discharge since her confinement, when previously she had been free from this annoyance. The history might be that of an attack of specific infection. Sometimes the history in such a case was clear—a sudden appearance of a yellowish vaginal discharge, with swelling of the labia and burning in micturition. At other times the evidence of specific infection was not entirely satisfactory, but it was notorious that women often became contaminated without giving the matter any particular attention, or the discomfort had been so

slight as to be soon forgotten. In any event, if the disease was neglected and spread to the cavity of the uterus, it soon spent its force and settled down to a chronic condition. It might or might not extend into the Fallopian tubes and cause salpingitis and peritonitis. Should it do so, as was often the case, the removal of the appendages would not necessarily bring about a cure of the patient. In fact, this was the secret of the failure of laparotomy in many cases. Even if the disease was complicated by pelvic disorders of an inflammatory nature, especially if the two arose from the same cause, it was well to first turn our attention to the endometritis, in which case a laparotomy might at times be avoided. In other words, in certain cases embracing the two diseases the symptoms of the endometritis might overshadow those of the salpingitis; this was especially true of many instances in which the intraperitoneal damage had not been very serious. In cases where the intraperitoneal inflammation had subsided, and only its products remained, the treatment of the endometrial inflammation, which, under these circumstances, was usually chronic, could be carried out with impunity if ordinary care was taken. Of course, in the event of there being an acute or even a subacute pelvic inflammation present, great care must be taken not to interfere with the uterus in any way, else an already bad condition of affairs might be made much worse, and even serious. In many patients in whom there existed post-puerperal septic endometritis or specific endometritis, the disease had stopped short of the tubes, and had not involved either them or the peritonæum. These cases were quite common, and were daily overlooked. The women wandered from one doctor's office to another, and finally, when their money was all gone, into the public clinics, seeking relief in vain. It was often a matter of surprise that many of them had never even had an examination made, but had been treated for months and years with drugs, or had been advised to use injections of hot water. The hot-water injections as usually given were worse than useless. Just sufficient water at a moderate temperature was used to cause a congestion of the uterus and pelvis, which congestion was not relieved by the secondary effect of the hot water—*viz.*, the contraction of the blood-vessels and consequent driving away of the blood from the parts. These women suffered from a continual uterine discharge more or less profuse; there was, perchance, a feeling of weight and heaviness in the pelvis, accompanied by back-ache; sometimes they felt weak and worn out. The menstrual function was disordered, being generally irregular and profuse; pain might or might not attend this function. These symptoms existed either alone or in various combinations, the only constant and reliable one being the uterine discharge. A local examination disclosed an enlarged and heavy uterus, from the cervical canal of which an unhealthy thickish discharge was oozing. Oftentimes the cervix was eroded, and the mucous membrane of the everted lips, if the lips were everted, bled on being touched with a piece of cotton or an instrument. This hæmorrhagic condition was more apt to be present when the disease was still acute or subacute; but, nevertheless, it was at times seen in the chronic cases. In some instances the uterine body was comparatively normal to the touch so far as its consistence was concerned; again, it might be either too soft or, what was more common, extremely hard, and even almost fibrous in character. These changes indicated that the disease was not altogether confined to the endometrium, but had invaded the structures comprising the uterine wall. It was no uncommon thing to see an endometritis and a metritis coexisting; in fact, in chronic cases it was rather the rule than the exception. The disease was almost always primarily an endometritis, and treatment which would cure this affection would be followed by a cure of the metritis almost as a matter of course. So much was this the rule that the author had got to look on these two diseases as very much one and the same.

Where this condition of affairs existed—a large and abnormally heavy uterus—there was very apt to be a retro-displacement of the womb sooner or later. Whether or not all displacements which gave rise to trouble were originally caused by uterine inflammations, it was a curious fact that it was a very rare thing to find a troublesome retro-displacement without either uterine or pelvic inflammatory diseases complicating it.

For the treatment of uncomplicated endometritis and metritis there was a variety of remedies, some of them quite effective, while many of

them were useless and were applied in a haphazard way. His own preference was to adopt the shortest and surest course of procedure. The woman was etherized, the cervix dilated, and the uterus thoroughly curetted; the uterine cavity was then washed out, and an application of Churchill's tincture of iodine made to its surface. If there was pretty free bleeding in consequence of these manipulations, the uterus was packed full of iodoform gauze, which was removed in the course of a day or two, as circumstances demanded. Ergot might or might not be given by the mouth, the indications for its use being hæmorrhage or an enlarged, heavy uterus. Usually, the author gave half a drachm of the fluid extract three times a day for a short period, gradually reducing the quantity until it was dispensed with altogether within about a week.

As to the steps of the operation: The patient was placed in the dorsal posture, and the dilatation was made with the Goodell rapid dilators after careful antiseptic precautions—only sufficient to introduce and manipulate the instruments easily—from three quarters of an inch to an inch. Great care was taken to make the curettement a thorough one. All *débriis* could be washed away, and the cavity cleansed by the use of the rectal nozzle of a Davidson syringe. The application of iodine followed immediately by means of a long-nozzled uterine syringe. The patient was now returned to bed, and nothing more was done for a week or two, except to give absolute rest and hot-water injections, and keep the bowels soluble, together with the use of ergot as indicated. The author had not found occasion to place a hard-rubber drain in the uterus, as Wylie did, nor to pack it with iodoform gauze for a prolonged period, as Polk proposed. He found, if the dilatation had been properly made, that the cervical canal remained sufficiently patulous for the necessary drainage. The uterus would resent in one way or another the presence of a foreign body, and these procedures could only result in just so much more irritation and consequent discharge.

Some patients were cured altogether by this treatment; but, for the most part, in order to secure a thoroughly satisfactory result, treatment must be kept up for some little time after the woman was allowed to get out of bed. It was the author's habit, in these cases, to make an intra-uterine application of iodine about twice a week for a few weeks, then once a week, and finally to withdraw the treatment altogether; the hot-water injection should be kept up twice a day throughout the whole course of treatment. It was not uncommon, where the endometrium had undergone a fungous change, for the disease to return, and the whole treatment had thus to be gone through with a second time.

Many patients would not submit to this treatment, in which event it became necessary to resort to other methods of management. A prolonged course of intra-uterine treatment would, in many cases, eventually bring about the same result. The author did not maintain that iodine was the only remedy to be used for this purpose, but he had come to use it habitually for the reason that he had found no other drug which would give better results. It was not advisable always to use it in full strength, in which case it might with advantage be diluted with glycerin in the required proportions. Ichthylol and all similar substitutes had only proved disappointing.

So much for the uncomplicated cases of endometritis. Where the disease was accompanied by a pelvic inflammatory condition the first question to settle was whether or not an abdominal section was to be performed for the removal of the appendages. If they were not sufficiently affected to call for the operation, and if the uterine symptoms predominated and were very annoying, he had no hesitation in treating the uterine cavity. A long-nozzled uterine syringe might with safety be passed into the uterus, even in the presence of considerable pelvic disease, and a local application thus made. In these cases the strength of the material injected should be regulated by the amount of inflammation, as a strongly irritating fluid would be much more likely to cause trouble than the mere passage of the instrument itself. When the pelvic disease was an old one and quiescent he had no hesitation in gently dilating the cervix and curetting the cavity of the uterus, and he had never seen any trouble follow such a procedure. In this class of patients there was an opportunity for the nicest kind of judgment, and if one was skillful and careful in selecting the proper cases the

treatment might be followed by the greatest benefit. The author was perfectly well aware that this was contrary to the teachings of many gynæcologists of the present day, but his own experience in these matters had opened his eyes to the fallacy of such ideas. If the gentlemen opposing the practice of intra-uterine treatment would try it on some of their patients who continued to have enlarged uteri and a vaginal discharge after the removal of the appendages they would soon become convinced of its practical value, even in these cases.

**The Pathology of Genius.**—In an editorial article the *British Medical Journal* says:

Huxley defines genius as innate capacity of any kind above the average mental level. Accepting the definition that genius is an in-born tendency to do certain things better than most men, it may be called something abnormal, but to treat it as something pathological is neither new nor true. Nevertheless, there will always be people willing to believe that men favored by Nature with great mental powers have some compensating deficiencies. Genius is perhaps not so uncommon as some assume, but there is a great reluctance to recognize it. There have been men of genius who never gained distinction owing to adverse circumstances. There is always a goodly number of men who step beyond the line in physical and mental endowments, and this superiority is evidently inborn. So far is this from being a proof of any morbid condition, that perfection of function is the highest result of happy heredity and healthy nutrition.

Mr. Nisbet, who, a short time ago, wrote a book on the insanity of genius,\* does not venture to espouse the statement of Moreau that genius is a neurosis, but he holds that great mental gifts are not obtained, as a rule, without some disturbance of the brain and nervous system. In favor of this view he quotes, curiously enough, an opinion expressed by Professor Huxley to the effect that a genius among men stands in the same position as a "sport" among animals or plants. He thinks it probable that "a large proportion of 'genius sports' are likely to come to grief physically and socially, and that the intensity of feeling which is one of the conditions of genius is especially liable to run into the fixed ideas which are at the bottom of so much insanity." Mr. Nisbet is able to enumerate a rather long list of celebrated persons who suffered from diseases more or less remotely connected with the nervous system, but whether in a given number of men of genius more nervous disease would be found in them and in their families than in the same number of ordinary men living under similar circumstances is an inquiry which it would be very difficult to make. Mr. Nisbet makes the most of the fact that toward the close of his life Julius Cæsar had occasional epileptic fits; nevertheless, Julius Cæsar was a man of astonishing strength, both bodily and mental, but the strain to which he subjected his constitution from his ceaseless toils and his sensual excesses seemed sufficient to wear out any human organism.

On looking over Mr. Nisbet's list of neurotic great men we miss a large number against whom nothing can be said. He claims Alexander the Great as a neuropathic genius, on the ground that he had an affection of the muscles of the neck, which compelled him to hold his head on one side; and that a brother of his was an idiot. This must be Aridæus, son of Philip by a concubine, who is described as of feeble intelligence, but certainly not an idiot. Plutarch merely says that Alexander had a slight droop of the head, and that the weakness of Aridæus was not congenital, but Olympias destroyed his intellect with her drugs. Besides these two, no other of the great generals of antiquity are claimed as neuropaths. Mr. Nisbet seems satisfied if he can assign any defect or disease against a man of genius, or even against his ancestors. For example, he thinks it worth while to tell us that Southey's father was "passionately fond of field sports," and then observes: "Extraordinary physical energy is often found in connection with nerve disorder, the result of an excessive stimulation of the motor centers of the brain." We are told that Cromwell died of ague at fifty-nine, a "malady the exciting causes of which are still unknown, but which is obviously of a nervous character." Then Marlborough was

subject to headaches and giddiness; and Turenne had a weak constitution in boyhood, stuttered, and was subject to a convulsive movement of the shoulders. We hear nothing of Condé or other great French generals save Napoleon, as to whom we have the story of his being an epileptic. We are told that Wellington was also an epileptic. Certainly Marlborough, Napoleon, and Wellington were all men of very strong constitutions. All writers who have taken up this view about the unhealthy character of genius soon take us away to poets and painters, who are mostly men of extreme sensibility, and often leading strange and unconventional lives.

There have been, no doubt, too many sickly poets who have gained notoriety by gratifying a morbid taste for unwholesome reading, but Tasso seems the only great poet who ever was insane. Mr. Nisbet tells us he was confined for a time on account of homicidal mania. There is, indeed, a story of Tasso's drawing a knife on a man, but we do not know the provocation; and this is the only record of his trying to injure any one. The character of his insanity was certainly not homicidal mania.

To those who are willing to believe that the poet has a touch of insanity about him, Shakespeare is a great difficulty which Mr. Nisbet evidently prides himself in having done something to remove. He tells us that Masson has discovered that he (Shakespeare) "was, in his solitary hours, an abject and melancholy man." Three of the poet's sisters died in childhood, one brother in early manhood, and two others in what ought to be the prime of life. Mr. Nisbet informs us that the retirement of the great dramatist to Stratford-on-Avon when he was forty-eight was not owing to his having made a fortune, but owing to his health having broken down, and he assumes, without any adequate proof, that his last illness looks like successive shocks of nervous disorder. Mr. Nisbet gives us the choice between a paralytic or an epileptic seizure or paralysis agitans. As for his children, they either died in infancy or they were stupid. Judith must have been either capricious in her rejection of offers of marriage, or very unattractive, for she was thirty-two years of age before she secured her husband, Thomas Quiney, a vintner, not of good family nor particularly well-to-do. As for Susannah, who married Dr. Hall in her twenty-fifth year, she was a stupid woman who sold her husband's medical manuscripts without reading them. The statement that she was "witty above her sex" Mr. Nisbet regards as conventional "tombstone flattery." Suppressing the continuation of the epitaph, "More than all, wise to salvation was good Mrs. Hall," he observes: "Unfortunately, this is all that can be told to her credit." On the other side of the account, our author lets us know that Mrs. Hall was troubled in childhood with scurvy, and had a daughter who had tortura oris, inflammation of the eyes, and ague. So that we are bidden to insist no more about the healthy character of the genius of Shakespeare.

The observation that the families of men of genius have a tendency to die out could be better considered under the broader statement that aristocracies and families living in luxurious social conditions do not habitually keep up their numbers.

Mr. Nisbet's book is written for the general reader, but his subject will always have a great interest for medical men, who, however, will be cautious in letting their assent wander far beyond the evidence adduced. Perhaps if the author had been more careful in sifting his statements, and had presented his conclusions in less startling terms, his work would have had less attraction for the public.

**The Association of American Physicians.**—The next annual meeting will be held on Tuesday, Wednesday, and the evening of Thursday, May 24th, 25th, and 26th, in the Medical Museum and Library, Washington, D. C., under the presidency of Dr. Henry M. Lyman, of Chicago. The subject selected for discussion is Dysentery. Dr. William T. Councilman, as referee, will consider the etiology and pathology, and Dr. A. Brayton Ball, as co-referee, the symptomatology, complications, and treatment. Besides the president's address, papers are to be read as follows: Dr. Charles Carey, The Production of Tubular Breathing in Consolidation and other Conditions of the Lungs; Dr. Samuel C. Chew (title to be announced); Dr. William C. Dabney, A Contribution to the Study of Hepatic Abscess; Dr. I. N. Danforth, Tube Casts and their Diagnostic Value; Dr. George M. Garland, The Treatment of

\* *The Insanity of Genius and the General Inequality of Human Faculty physiologically considered.* By J. F. Nisbet. New Edition, Ward and Downey, 1891.

Follicular Tonsillitis; Dr. Heneage Gibbes, The Morbid Anatomy of Leprosy; Dr. Hobart A. Ilare, A Collective Investigation in regard to the Value of Quinine in Malarial Hæmaturia or Malarial Hæmoglobinuria; Dr. A. Jacobi (title to be announced); Dr. W. W. Johnston, The Treatment of Acute Dysentery by Antiseptic Colon and Rectal Irrigation; Dr. Thomas S. Latimer, Alcoholism; Dr. Morris J. Lewis, A Study of the Seasonal Relations of Chorea and Rheumatism for a Period of Fifteen Years; Dr. Morris Longstreth (title to be announced); Dr. Francis T. Miles, A Case presenting the Symptoms of Landry's Paralysis, with Recovery; Dr. William Pepper, Report of a Case of Glanders, with Results of Bacteriological Study; Dr. T. Mitchell Prudden (title to be announced); Dr. George M. Sternberg, Practical Results of Bacteriological Researches; Dr. Charles G. Stockton, Misconceptions and Misnomers revealed by Modern Gastric Research; Dr. William H. Thomson, The Significance of Intermision in Functional Nervous Diseases; Dr. Victor C. Vaughan, Certain Toxicogenic Germs found in Drinking-water; Dr. B. F. Westbrook, Studies in Hypnotism; Dr. James C. Wilson, Pulsating Pleural Effusions; and Dr. George Wilkins, The Cold-water Treatment of Typhoid Fever. Members wishing to present papers are requested to send their names, with the title of the papers, to the secretary, Dr. Henry Hun, 33 Elk Street, Albany, N. Y. Papers can be read by title at the meeting and appear in the volume of Transactions. The Constitution of the association (article VI, sections 4 and 5) provides that authors of papers, and referees and co-referees, who open a discussion, shall not occupy more than thirty minutes each; and in the discussion following, the remarks of each speaker shall be limited to ten minutes. The referees, co-referees, and authors of papers shall send abstracts of their papers to the council for distribution to the members previous to the meeting. This provision, however, does not preclude a fuller or more detailed presentation of the subject in the articles prepared for the Transactions, but the limits of time prescribed for the reading of the papers will be enforced.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. Walter Wyman, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for March 4th:

**The Treatment of Chorea with Exalgine.**—According to the *Semaine médicale*, Dr. H. Löwenthal, of Berlin, in a recent paper gave the details of thirty-five cases of chorea treated with exalgine. The results were very encouraging. The dose employed was three grains, repeated three to five times a day; the duration of treatment varied, according to the gravity of the case, from eight days to four months. The results were obtained the most rapidly where the treatment was begun at the onset of the disorder. In some of the cases considerable amelioration was established after twelve doses (36 grains) of exalgine had been given, but in the majority double this number of doses was

necessary before improvement was manifested. One child, of eight years, was completely cured after twelve doses of 3 grains each. The greatest quantity of the drug employed was in a severe case, in which about 1,700 grains were given in the course of more than three months. In cases where the choreic movements were very violent the condition of the patient was aggravated, in spite of the exalgine, for the first two weeks of treatment, to be ameliorated afterward, slowly, but progressively, until they were arrested. In addition to its action on the muscular movements, the medicament influenced also very favorably certain other nervous phenomena, such as the mental excitement, feebleness of memory, salivation, articular pains, and formication in the fingers and arms. These symptoms improved very rapidly during the first week of treatment. The drug was often well supported, but frequently, after its prolonged use, ringing in the ears, nausea, cephalalgia, and vertigo were complained of. In four cases there appeared a generalized icterus. None of these phenomena were ever of a serious nature, and they required no treatment other than the temporary suspension of the use of the drug. After their disappearance the exalgine was again given without the reappearance of the unpleasant symptoms. In conclusion, M. Löwenthal expresses the opinion that exalgine should be placed among the antichoreic remedies.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

CYST OF THE MIDDLE TURBINATED BONE.\*

BY CHARLES H. KNIGHT, M. D.,  
NEW YORK.

THE middle turbinated body may become of pathological importance in various ways. Aside from malignant disease and syphilis, which are prone to attack this structure in common with other intranasal tissues, the lesions of this body with which we usually meet may be divided into two classes—those involving its mucous membrane, and those affecting its bony framework. The former are more frequent and are more remediable, since osseous changes are always associated with an advanced degree of disease of the mucous membrane.

The object of the present paper is to add to the literature of a very interesting pathological change in the bony framework of the middle turbinated body, which, notwithstanding its frequency, has had but little notice. Many years ago one of my associates at the Manhattan Eye and Ear Hospital called my attention to a singular condition of a middle turbinated body which he had just removed with a cold-wire snare. We found that the loop had cut through a mass of polypoid tissue attached to a bony shell, presenting a depression in which the tip of the little finger could readily be placed. The bone was for the most part extremely thin, so that in the process of cutting through the mass the existence of osseous tissue was not recognized. The mucous membrane externally, which had not undergone polypoid degeneration, was in a state of decided atrophy. The interior of the cyst was lined by a pale, thin membrane. No attempt was then made to examine the tissues microscopically. Since that time numerous similar instances have come under my observation, and my friend Dr. W. H. Park has been kind enough to make sections and give me the results shown by the microscope. For the photographic reproductions I am indebted to my assistant, Dr. W. P. Brandegee. The illustrations show a side-view

FIG. 1.—Cyst of right middle turbinated bone. External surface.

FIG. 2.—Cyst of right middle turbinated bone. Interior.

and a view of the interior of one of the largest of these cysts with which I have met.† The patient from whom it was obtained was a middle-aged woman, whose right nostril was completely occluded by a mass which could easily be seen without a speculum when the tip of the nose was

raised, and which at first glance appeared to be a large myxoma. But on palpation it was found to be hard and resistant, and there was no sign of a polypoid condition of the mucous membrane. On the contrary, the soft parts were atrophied. The septum was somewhat deviated to the left, and there was some hyperplasia of the mucous membrane in the left naris without apparent bony change.

The subjective symptoms complained of were impeded nasal breathing, impaired sense of smell, and persistent headache. The voice had a slightly nasal quality and there was considerable annoyance from post-nasal discharge. The obstructed nostril was freed by means of the cold-wire snare and cutting forceps. The portion removed with the snare and shown in the photographs measures an inch and a quarter in its antero-posterior diameter, half an inch vertically, and half an inch laterally. The greatest depth of the cyst through which the wire passed was five eighths of an inch. The part removed with the snare represents only about two thirds of the entire cyst. The remnant was removed with cutting forceps so as to relieve all pressure and obstruction and permit free drainage. The patient experienced great relief from the operation, which was done under cocaine, and was followed by no unfavorable developments.

The clinical history in cases of this kind must of course vary with the degree of enlargement. In nearly every case the symptoms most prominent are those referable to pressure from the distending cyst, such as hemicrania and neuralgias of the fifth pair. These reflex neuroses were especially marked in cases described by Glassmacher,\* McBride,† and others. The most serious complication likely to arise, and one more apt to occur if myxomata coexist, is empyema of one or more of the adjacent sinuses, obstruction of the *ostium maxillare* being a frequent cause of antral disease. It is a remarkable fact that this cystic transformation but seldom involves the inferior turbinated. I have myself never seen it except in the middle. A single case has been reported by Schaeffer‡ in which the inferior turbinated was affected, and Bayer has reported a case in which the superior turbinated was involved. It is also noticeable that in a certain proportion of cases the condition is associated with well-defined myxomata or polypoid degeneration. In my experience more than half the cases presented this feature, and in every case there was more or less atrophy of the mucous membrane. Children seem to be exempt. None of my own patients was under twenty years of age, most of them were past middle life, and the majority were females. This condition requires to be distinguished from osteoma, myxoma, and mucocele of the ethmoidal cells. But little difficulty should be found in reaching a correct conclusion if we carefully observe the origin and situation of the tumor, its immobility, its hardness and at the same time its fragility, and possibly its translucency (Zwillinger). Osteomata are harder and do not permit of penetration by means of the exploring needle, and, moreover, are said to

\* Read before the American Laryngological Association at its thirteenth annual congress.

† (Zueckerandl, whom nothing in nasal pathology seems to have escaped, shows a typical example of this deformity in his classical work, *Normale und patholog. Anatomie der Nasenhöhle*, Tafel 2, Fig. 6.)

‡ *Chir. Erfahrungen in der Rhinol. und Laryngol.*, Wiesbaden, 1885.

be movable at their inception. Myxomata are freely movable, are soft and yielding, and are generally multiple. Mucocoele of the ethmoidal cells is a rare condition, presenting many of the features of ordinary myxoma, and could hardly be mistaken for a bony tumor.

The method of preparing the specimen for microscopic examination was as follows: The cyst was kept for eighteen days in a saturated solution of picric acid, and was then washed out in alcohol. It was then placed in absolute alcohol for twenty-four hours, then transferred to equal parts of absolute alcohol and ether, in which it was retained another day, and finally was immersed for twenty-four hours in a solution of celloidin in absolute alcohol and

cells, and quite vascular. This structure is rather more dense in the immediate neighborhood of the bone. The thickness of the bone varies greatly in different regions, and distributed along its inner surface may be seen a row of osteoblasts. Lining the bone is a layer of loose œdematous connective tissue resembling myxomatous tissue. Finally, a complete row of columnar ciliated epithelium lines the inner wall of the cyst.

Two theories have been advanced in explanation of this condition. The first is that it is a result of a rarefying osteitis, similar to that occurring in the long bones. The second theory, recently sustained by Greville Macdonald, supposes the lesion to have its origin in an osteophytic

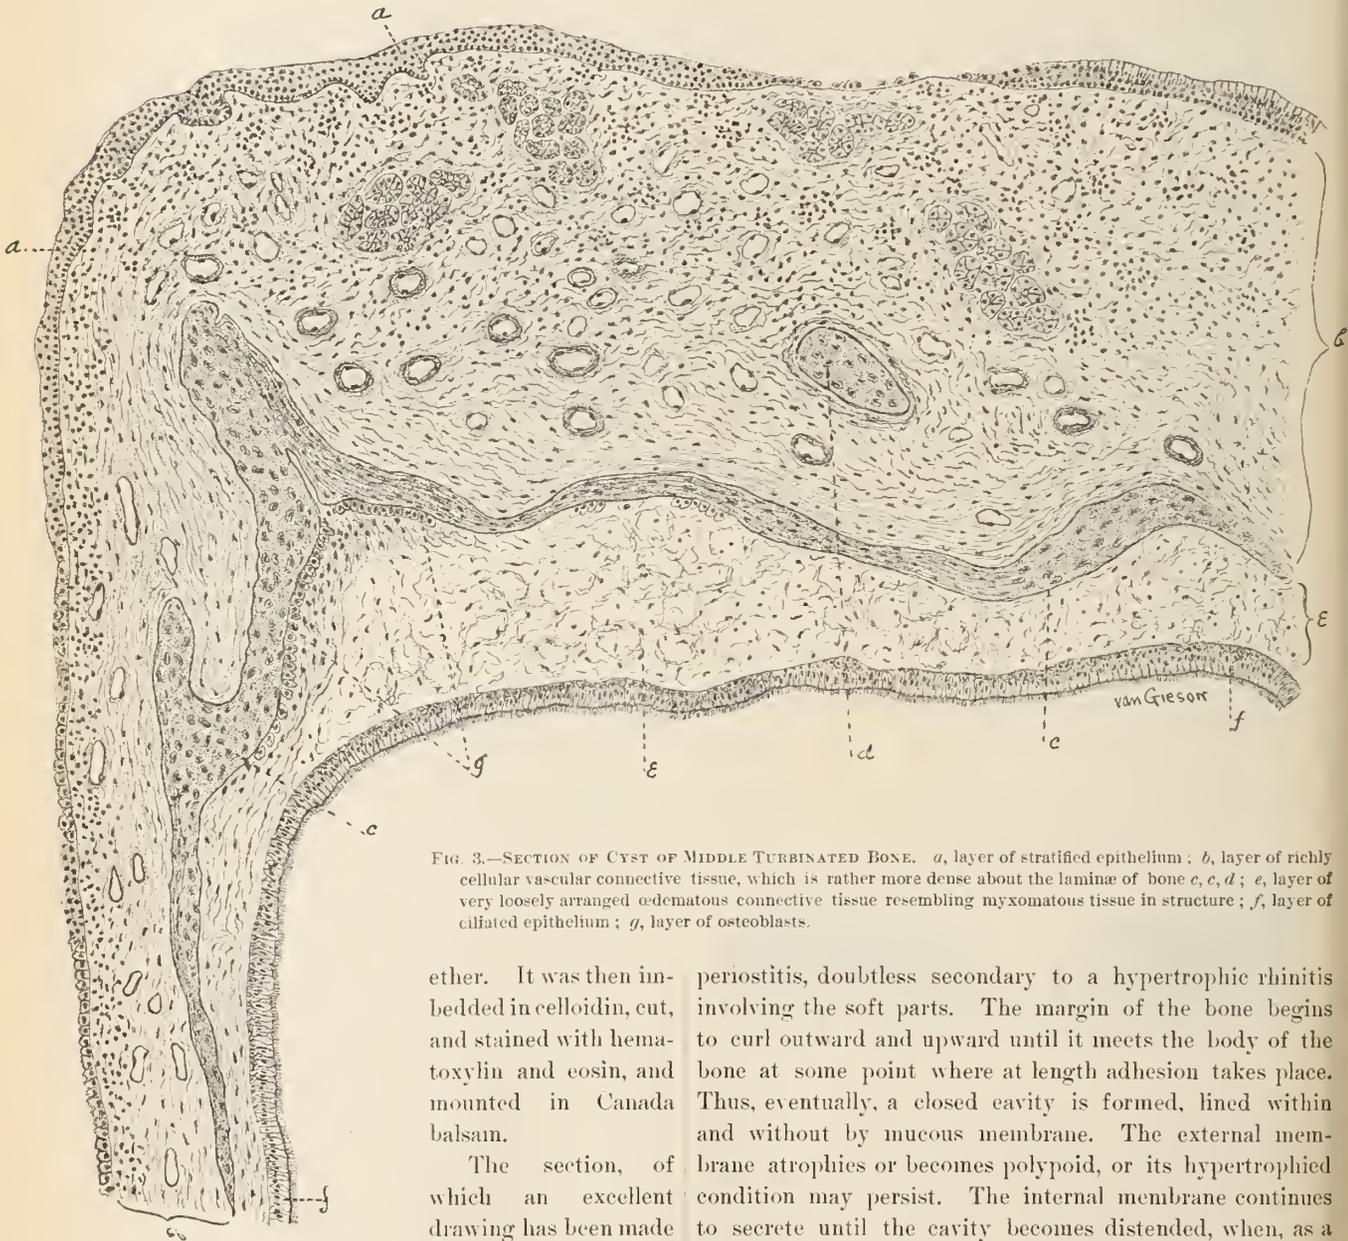

FIG. 3.—SECTION OF CYST OF MIDDLE TURBINATED BONE. *a*, layer of stratified epithelium; *b*, layer of richly cellular vascular connective tissue, which is rather more dense about the laminae of bone *c, c, d*; *e*, layer of very loosely arranged œdematous connective tissue resembling myxomatous tissue in structure; *f*, layer of ciliated epithelium; *g*, layer of osteoblasts.

ether. It was then imbedded in celloidin, cut, and stained with hematoxylin and eosin, and mounted in Canada balsam.

The section, of which an excellent drawing has been made by Dr. Van Gieson,

consists of one half of a small and probably recent cyst, which has been cut vertically at a right angle to its long axis. Examined from without inward, we find externally a layer of stratified epithelium, then a layer of connective tissue of considerable thickness, rich in

periostitis, doubtless secondary to a hypertrophic rhinitis involving the soft parts. The margin of the bone begins to curl outward and upward until it meets the body of the bone at some point where at length adhesion takes place. Thus, eventually, a closed cavity is formed, lined within and without by mucous membrane. The external membrane atrophies or becomes polypoid, or its hypertrophied condition may persist. The internal membrane continues to secrete until the cavity becomes distended, when, as a result of pressure, the glandular elements undergo absorption and the membrane becomes very much attenuated. In some cases the lining membrane will be found to have become polypoid and granulating, giving rise to the formation of pus, perhaps in sufficient quantity to simulate abscess. Macdonald, in an article on Cyst and Abscess of the

Middle Turbinate Bone (*Lancet*, London, June 20, 1891), remarks that abscess "may possibly originate in a cyst produced by retained secretion." The contents of these cysts vary in character. The name given them by French and German writers implies that they contain air, which is doubtless generally the case. But it is equally true that they sometimes contain fluid, mucous or purulent, as the case may be. Unless one could remove a cyst unbroken, which I never have succeeded in doing, it would be somewhat difficult to determine the quality and quantity of its contents. The manipulations attending its removal must of necessity provoke secretion and obscure its source. In some cases the cyst is multilocular, or its cavity is traversed by numerous bands of bony or membranous tissue. Bayer (*Rev. mens. de laryngologie*, etc., June 1, 1885) minutely describes a multilocular cyst of the right middle turbinated bone which he punctured with the galvano-cautery. The tumor occluded the naris and displaced the septum. It finally disappeared, and the parts regained their normal contour in the course of two months, after repeated applications of the galvano-cautery and the use of injections of chloride of zinc and phenic acid. A remarkable feature of this case was a recurrence of cystic degeneration involving not only the middle but the superior turbinated as well. In the largest of the specimens exhibited and shown in the photographs, the wall of the cyst is quite thick on one side and honeycombed. Elsewhere it is thin as tissue paper. It is difficult to conceive that the appearance depicted in this particular specimen could have been developed in the manner suggested by the second theory. On the other hand, I have met with several cases in which the cyst was as yet incomplete and apparently in course of formation by this process of curvation. The existence of columnar epithelium provided with cilia still further supports, and indeed may be said to prove, the second theory. At the same time other conditions can be satisfactorily explained only by assuming an inflammatory process in the bone itself.

The indications for treatment are clear enough, and may be enumerated as follows:

1. Interference with nasal respiration.
2. Prevention of nasal drainage.
3. Reflex neuroses.
4. Anosmia.
5. Impaired quality of voice.

Unless the cyst is so large as to cause pressure or impede nasal breathing, it is seldom necessary to interfere. The bone is usually so thin that it may easily be crushed with forceps if desirable, and redundant tissue may be removed with cutting forceps. In large cysts, especially if associated with polypoid growths, the cold-wire snare will be found to be most serviceable. Schmiegelow,\* who has carefully described this condition under the name "*transformation kystopneumatique*," prefers to puncture the cyst with the galvano-cautery and remove its walls to the necessary extent with cutting forceps and scissors. A similar method is advocated by Zwillinger,† who reports two cases,

and who claims to detect the presence of the cyst by transillumination and puncture. In my experience a diagnosis is usually possible without resorting to either of these methods, and the advantage of the galvano-cautery over other procedures as a mode of treatment is not apparent. The pain of the operation, in spite of the free use of cocaine, is sometimes considerable, and subsequent reflex neuralgias are not infrequent. Hæmorrhage is seldom excessive, and in several of my cases it was surprisingly scanty.

20 WEST THIRTY-FIRST STREET.

## THE REMOVAL OF NECROTIC AND CARIOUS BONE WITH HYDROCHLORIC ACID AND PEPSIN.\*

BY ROBERT T. MORRIS, M. D.

SOMETIMES it is desirable to remove dead bone without subjecting a weak patient to a dangerous or deforming operation. Attempts have been made with some success at clearing out this bone by a process of decalcification, but there are two chief reasons why failures have resulted as a rule. In the first place, it was discovered that superficial layers of dead bone were decalcified easily enough, but the acids did not reach deeply through the mass, especially if portions were infiltrated with caseous or fatty *débris*. In the second place, cellulitis was pretty apt to develop during the course of treatment. After much experimentation I have finally adopted a method of work which seems to be complete. An opening is made through soft parts by the most direct route to the seat of dead bone, and if sinuses are present they are all led into the one large sinus if possible. The large direct sinus is kept open with antiseptic gauze and the wound allowed to remain quiet until granulations have formed.

Granulation tissue contains no lymphatics, and absorption of septic materials through it is so slow that we have a very good protection against cellulitis. The next step consists in injecting into the sinus a two- or three-per-cent. solution of hydrochloric acid in distilled water. If the patient is confined to bed, the injections can be made at intervals of two hours during the day; but if it is best to keep the patient up and about, the acid solution is thrown into the sinus only at bed-time. In either case the patient is to assume a position favorable for the retention of the fluid. Decalcification takes place rapidly in exposed layers of dead bone, and then comes the necessity for another and very important step in the process. At intervals of about two days an acidulated pepsin solution is thrown into the sinus (I use distilled water, f ʒ iv; hydrochloric acid, ʒ xvj; Fairchild's pepsin, ʒ ss.), and this will digest out decalcified bone and caseous or fatty *débris* in about two hours, leaving clean dead bone exposed for a repetition of the procedure. The treatment is continued until the sinus closes from the bottom, showing that the dead bone is all out.

Even in distinctly tuberculous cases the sinuses will

\* *Rev. de laryngologie*, etc., May 15, 1890.

† *Wiener klin. Wochenschrift*, No. 19, 1891.

\* Read before the Southern Surgical and Gynecological Association, November 12, 1891.

close if apparatus for immobilizing diseased parts and tonic constitutional treatment are employed, as they should be in conjunction with our efforts at removing the dead bone.

If suppuration is free in any cavity in which we are at work, it is well to make a routine practice of washing out the cavity with peroxide of hydrogen before each injection.

It is a popular impression in the profession that living bone is not attacked by dilute mineral acids, but, as it makes a good deal of difference whether the impression is correct or not, I experimented as follows: A portion of the keratinoid layer was removed from the carapace of a turtle (*Nanemys guttatus*), and the animal was then placed tail downward in a glass of five-per-cent. hydrochloric-acid solution. In the same glass I placed also a segment snipped from the plastron of the turtle, and a transverse section of an old dried humerus of a man. The piece of humerus was completely decalcified in six hours, the segment from the plastron was soft in about twenty hours, and the carapace of living bone was decalcified at the exposed part in thirty hours. I was then curious to know what effect the acid had had upon the blood-vessels of the decalcified bone, and Dr. Smith, of the laboratory of the Post-graduate Medical School, made for me several sections of the carapace which included both decalcified and healthy bone. Investigation showed that all of the blood-vessels were destroyed wherever the bone was softened, and the action of the acid had extended farther up along the larger blood-vessels than elsewhere. In the accompanying photomicrographs the dark

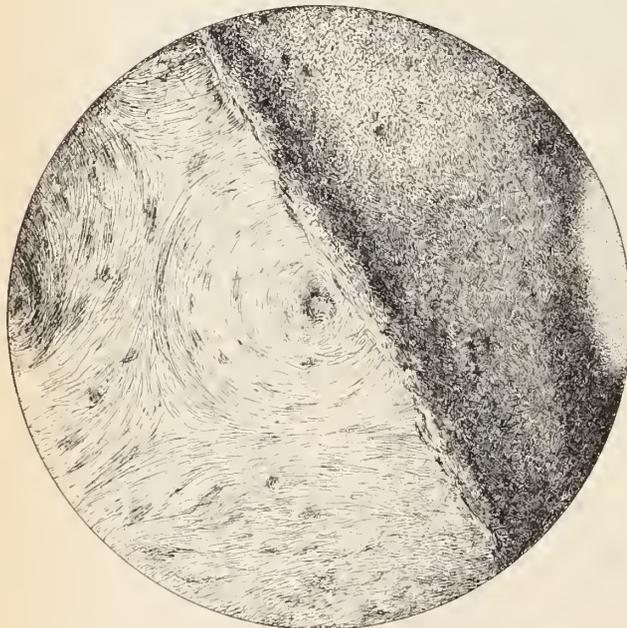

FIG. 1.

portions represent decalcified bone stained with carmin, and in the lighter portions the structure of the normal bone cells is readily distinguished. In Fig. 2 can be seen the line of extension of decalcification along three blood-vessels.

The difference in time between decalcification of the dead bone (six hours) and of living bone (thirty hours) is significant, a five-per-cent. solution of hydrochloric acid having been used.

If we use a two- or three-per-cent. solution of hydrochloric acid, a wall of lymph and of granulation tissue is

FIG. 2.

thrown out upon the surface of living bone for protection, and only dead bone is attacked. This at least has been my observation in several cases in which the results of treatment could be easily watched.

The details of treatment in some of the cases would be very interesting, but if the paper were lengthened to accommodate them my main points would be apt to hide.

## SUPERFICIAL PAPILLOMA OF THE OVARY.

WITH REPORT OF A CASE.

By STEWART PATON, M. D.

SINCE Proschaska reported his first case the literature relating to superficial papillomata of the ovaries has steadily increased. A few years ago it was very small, but the reason for this somewhat rapid increase is not difficult of explanation. The pathologist is particularly interested in the development of these tumors, for structurally they may be considered as on the border-line between benign and malignant growths, and therefore the question of their innocence or their varying degrees of malignancy and the possibility of recurrence after removal is of especial import to the surgeon. The term malignant as applied to this class of tumors is certainly an unfortunate misnomer, as it is misleading. Unquestionably these tumors recur. Starting from the ovary, growths may occur on the uterus, tubes, broad ligaments, bladder, and the various reflections of peritoneum, but recurrence takes place by direct implantation and not by metastasis. I have carefully searched all records for evidence of metastasis occurring with papillomata, but have failed to find any reliable evidence to this effect. Certain forms of truly malignant growths, such as the cauliflower-like forms of carcinomatous tumors, may and have been mistaken on superficial examination for papil-

lomatous excrescences—"les excroissances dendritiques"—and only the microscope can distinguish them. There is no more clinical evidence for calling papillomata malignant than there is for placing myxo-adenoma of the ovary in the class of malignant neoplasms.

Unquestionably papillomata have a decided tendency to become malignant if their growth is uninterfered with for years, but cases which have been under observation for a considerable period, such as Doran's case, seven years, or those of Marchand and Coblenz, have never shown any tendency to recur after removal. In one case recorded by Marchand there was, in addition to the papilloma of the ovary, a coexistent carcinomatous mass on the omentum. Both tumors were removed, but the carcinoma subsequently recurred. The record of the microscopical examination of the ovarian tumor is incomplete and I should be inclined to regard it as a carcinomatous growth and probably an illustration of that class of cases already alluded to where the gross similarities are so marked that a purely malignant tumor has been mistaken for a benign growth. This view is evidently corroborated by the fact that there was "a well-defined carcinomatous growth on the omentum." Apart from this negative evidence that ovarian papillomata are not truly malignant growths, we have somewhat more positive evidence in the histogenesis of these tumors. Under the microscope the dissimilarity between the mode of development of papillomata and that of the embryonic carcinomata and sarcomata is very striking. In any carefully prepared series of sections of the former we can see in the disposition of the blood-vessels in relation to the surrounding cells a dependence of the new tissue upon definite vascular channels for blood-supply. To use a simile for clearness, the new tissue is not cut off from a basis of food supply. Contrast with this the process of tissue formation in any malignant growth of the ovary or of any other organ. The cell infiltration is characteristic. Each cell may be looked upon as a distinct entity, and the process of their development is discrete as considered in its relation to the whole tumor. Nothing is more distinctive of malignancy, nothing is more trenchantly defined than the absence of this cell autonomy in the growth of papillomata. The new tissue is formed in intimate dependence upon the

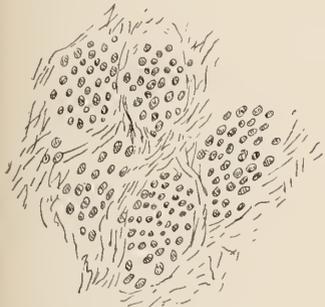

FIG. 1.—Cancer of the ovary.

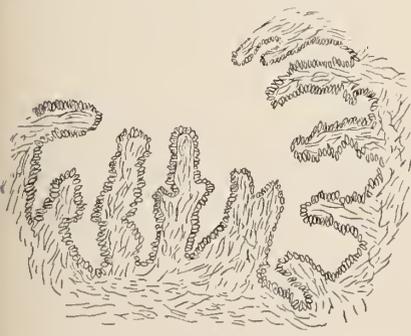

FIG. 2.—Papilloma of the ovary.

vascular supply; there is no cellular invasion, no metastatic diffusion, at least no case reported where the observations are free from question regarding their accuracy. Regarding papillomata as highly organized benign neoplasms, I have been unable to find a single case in which there has been a succession or recurrence of the growth in a more lowly organized but malignant type.

The importance of this is great, not as a proof that these growths would not have a malignant tendency if left untouched, but rather as an encouragement to the surgeon in attempting their removal. Recent observations point to something more even than the non-succession of malignancy. In the list of recorded cases where the peritoneal cavity has been thoroughly washed and drained there has been no recurrence of the papilloma, showing that the development of the implantations which occur in the majority of cases, and which it is often impossible to remove, has been successfully interrupted. It is particularly interesting to note that in the cases where recurrence after removal has been noted no mention is made of the fact that the abdominal cavity was drained after removal of the tumor. Naturally any implantations which existed at the time of removal and were overlooked develop, and consequently the records of such cases are practically worthless. I have been unable to find the record of any recurrence *in situ*. The removal with subsequent drainage of the peritoneal cavity undoubtedly prevents recurrence, at least as far as present records can determine the question for us. Drainage is all-important. It is often impossible to tell whether implantations have taken place, and if they have, of course, mere removal of the primary growth is not sufficient. If implantations have been left undisturbed, the thorough washing out of the peritoneal cavity apparently prevents the development of offshoots from the original tumor. Considering the great difficulty of completely removing papillomata, owing to their almost brittle character, the importance of always thoroughly washing out the abdominal cavity with distilled water and the employment of drainage-tubes can not be too strongly emphasized. In view of the rapid development of papillomata and the long continuance of symptoms, in some cases extending over a period of several years, we can not fail to note, even in the cases of longest standing, the absence of anything like an attendant cachexia. This is a point of minor importance, but still is worthy of attention. Apart from the local abdominal disturbances, such as ascites, pressure symptoms, menstrual disturbances, some pain, and the inconvenience afforded by the pressure of the tumor, patients suffer comparatively little. The symptoms are local. Too much stress must not be laid on this, however, for the absence of cachexia is often noteworthy in malignant cases. It is in the study of the histogenesis of these tumors and the correlative consideration of their clinical history and symptoms that we find considerable evidence of their primarily benign character. Striking confirmation of this is apparent in the following case, for the record of which I am indebted to Dr. T. Gaillard Thomas:

The patient was twenty-nine years of age; had been married six years. Had had one child, three years before; no miscarriage. She complained of dysmenorrhœa for several years prior

to becoming pregnant; since birth of child menstruation has been regular. On November 10, 1890, without any known cause, had an attack of subacute peritonitis, which lasted for two weeks. After the cessation of pain ascites rapidly developed. Since then the patient has been tapped thirteen times, and each time ten to thirty pints of clear serum were removed. Since the first appearance of the ascites the patient's general health has not suffered. Her appetite was unimpaired and her general strength was good. On October 9th the abdomen was opened and twenty pints of clear serum were removed; then with considerable difficulty a papillomatous mass, including both ovaries and the left tube, was torn loose from its attachments in Douglas's pouch. On superficial examination the mass was plainly papillomatous. Both ovaries were slightly enlarged. Their surfaces were covered with pedunculated outgrowths with pointed or rounded ends. The microscopical examination showed very clearly what has already been indicated in speaking of the histogenesis of these tumors, the absence of cellular invasion, and the evident dependence of the new-formed tissue upon definite vascular supply. Incidentally we may note the papillomatous mass connected with the right tube, as in the case reported by Doleris. The clinical symptoms of the case are interesting and show some points of importance in aiding in diagnosis.

As in this case, the majority of cases begin with symptoms resembling those of subacute peritonitis. These subside, then generally there is a rapid development of ascites with few other symptoms, the patient's general health being only very slightly impaired. As regards age, an examination of the records shows that no age is exempt; further than this, it is not safe to draw inferences, for the records of cases are yet too small in number.

## A REPORT OF CASES OF GLAUCOMA OF DIFFERENT VARIETIES, ILLUSTRATING SOME OF THE USUAL MEANS PRACTICED FOR THEIR RELIEF.\*

BY OREN D. POMEROY, M. D.,  
 NEW YORK.

CASE I.—Miss McG., aged twenty five, had acute inflammatory glaucoma of the right eye of ten days' duration. The eyeball was very hard, much congested, and so painful that she had not been able to sleep for more than a week. Iridectomy was promptly done under ether. Complete relief was at once obtained from all the symptoms. The vision was not much lowered, but it quickly returned to the normal.

CASE II.—Mrs. R. M., aged forty-eight, received a penetrating wound in the right cornea from a carpet tack. The lens was penetrated and soon became so swollen as to fill the anterior chamber. Increased tension of the eyeball and great pain resulted.

This lens matter was extracted through a corneal incision and the patient was at once relieved.

Both eyes were bandaged after the operation.

Four days subsequent to this the left eye was observed to have defective sight, she being able only to count fingers at four feet.

The corneal epithelium was somewhat hazy and the eyeball too hard.

It being evening, an iridectomy was done by lamp-light without difficulty.

The patient at once completely recovered, the vision and increased tension being restored to the normal.

CASE III.—Robert R., aged forty-one, was struck on the left eye by a piece of iron rust from a hammer; this lodged in the cornea and was removed by a fellow-workman. The eye was very painful, but the removal did not relieve the pain; the patient still continued to work.

The accident occurred three weeks previous to this observation. Four days subsequent to his first visit to the hospital he was again struck on the same eye by a piece of emery; this was at once removed, but intense pain still continued. Atropine was found to aggravate the pain; warm water was used to bathe the eye. In a day or two the eyeball had increased tension, the cornea was hazy and anæsthetic, the anterior chamber was shallow, and the pupil was widely dilated. There was considerable circumcorneal injection. The vision was =  $\frac{5}{6}$ .

Eserine solution was instilled and on the same day the pain disappeared, the pupil promptly contracted, the cornea began to clear, and the vision at once became doubled.

Improvement continued for a few days, but on March 25th it was thought proper to perform a sclerotomy, which was accordingly done. Eserine was continued.

On April 7th the tension was normal and the vision =  $\frac{2}{12}$ , whereas on March 9th it was only =  $\frac{5}{6}$ .

CASE IV.—Marg. M., aged sixty. Ten years since an iridectomy was done on the left eye.

Two weeks ago a severe pain appeared in the right eye, which has continued to the present time (July 10, 1891). There is intense ciliary congestion, steamy cornea, and shallow anterior chamber. The intra-ocular tension is increased. The nerve can not be seen. She counts fingers at six inches. Eserine was ordered to be instilled three times daily. In three days the pupil had contracted and the tension was diminished. Continued eserine and a leech to inner canthus, the latter repeated on the next day, which afforded some relief. July 18th, the tension being increased, injections of pilocarpine were used, leech repeated, and eserine continued. July 24th the tension is normal, pupil smaller. Eserine was continued. On July 28th the patient was discharged. It seems to the writer that the pilocarpine exerted an important influence upon the patient. Subsequent vision was not recorded.

CASE V.—Mrs. M., aged sixty-eight, had had attacks of inflammatory glaucoma in both eyes, with all the symptoms of the disease for several years. After three years the left eye became sightless and very hard. During the attacks of pain, relief, more or less complete, resulted from paracenteses of the corneæ, especially of the right. At the last bad attack of the right eye, the cornea becoming so opaque that little sight remained, iridectomy was reluctantly consented to and was done under ether on both eyes. The right recovered promptly and vision reached  $\frac{2}{12}$  and so continued for ten years, until her death. The left eye continued painful after the iridectomy for two weeks, when it was removed and found to contain an enormous blood clot. It is worthy of remark that the repeated paracenteses, at least a dozen, contributed greatly to the relief of pain during the exacerbations.

\* Read before the Medical Society of the State of New York at its eighty-sixth annual meeting.

CASE VI.—Henry M., aged sixty-four, has had chronic inflammatory glaucoma in each eye since a year. The tension is increased in both eyes. He counts fingers at three feet with either eye. The visual fields are much narrowed. Optic nerves are cupped with beaked vessels. Eyes moderately painful. An iridectomy was done on both eyes without affecting the tension. In four weeks sclerotomy was done, which restored the tension at once to the normal. The vision and the visual fields were unaffected.

CASE VII.—Miss S., aged forty-six years, has signs of chronic inflammatory glaucoma in the left eye dating back three months. The cornea is slightly hazy; the pupil somewhat dilated; the nerve shows glaucomatous excavation. The field is somewhat limited, and the tension is increased.

There is some circumcorneal injection, with moderate pain, which, however, is not constant. The vision =  $\frac{20}{155}$ . The other eye is normal and emmetropic.

Iridectomy was done under ether. The pain was relieved and the tension restored to the normal, but no other effect was produced.

This was one of two cases of glaucoma where the cornea was penetrated, in doing the iridectomy, with great difficulty.

CASE VIII.—Hannah W., aged sixty-five years, was awakened in the morning, about three months since, with a severe pain in the left eye; there was also some pain in the right eye. There was failure of sight in both eyes, but more so in the left.

On entering the hospital the vision of the left eye was =  $\frac{20}{200}$ . The right eye was =  $\frac{20}{200}$ . Both eyes were hypermetropic. The left has been painful since first being attacked.

The anterior chamber was shallow, and the pupil was somewhat dilated and sluggish. There was incipient cataract. The optic nerve showed signs of atrophy. There were flame-shaped hæmorrhages in the retina.

There was concentric limitation of both visual fields. Neither nerve showed glaucomatous excavation. The tension in the left eye was much increased; the right less so.

On June 16th sclerotomy was done on the left eye. It was feared that an iridectomy might induce an intra-ocular hæmorrhage.

After withdrawing the narrow cataract knife everything was as usual for a few seconds, when suddenly the anterior chamber was obliterated, and the iris prolapsed at either angle of the incision. These prolapses were removed by the scissors. Intra-ocular hæmorrhage was the natural explanation of this phenomenon. There was now only weak perception of light.

The operation resulted in quieting the pain and reducing the tension to the normal. Ten days subsequently there was pain in both eyes, and a one-grain solution of eserine was used in each four times a day. This pain continued for a week.

After its subsidence the patient was sent home, but was directed to report at the daily clinics.

Twelve days afterward (July 19, 1891) there was slight increase of tension and a little pain. On December 3d returned. She has had occasional pain in both eyes, but it has been relieved by a one-per-cent. solution of cocaine. The vision of the right eye =  $\frac{20}{200}$ ; that of the left is equal to counting fingers at six inches.

April 25, 1891.—The right eye is painful and has increased tension. A one-grain solution of eserine quickly relieved the pain and increased tension.

During the last six months the increased tension and the pain have been kept down by the eserine. The left eye has now no perception of light.

CASE IX.—Frank L. P., aged thirty-two years, applied for treatment on November 1, 1891, stating that for a year he had had dimness of vision in the right eye. There was some pain

and a feeling of soreness in the eye when excessively used. The vision =  $\frac{1}{2}$  with -1.50 D. The vision of the left =  $\frac{20}{20}$  with the same correction. A posterior polar cataract in the right eye caused a scotoma of from 10° to 20° in diameter. The field was concentrically limited to from 45° to 80°. The iris was sluggish. The tension was increased. A one-grain solution of eserine was used three times a day. Oleate of mercury was used with a view to constitutional effects. On November 14th the tension was normal and the patient was discharged.

On December 5th the tension was increased and there was some pain, but the vision =  $\frac{20}{20}$ . Paracentesis of the cornea was done with temporary improvement. By the 15th the symptoms had disappeared.

In a few days, however, there was increased tension and pain, and an iridectomy was done. In ten days all the symptoms had again disappeared.

On the 29th there was some intolerance of light, with conjunctival injection, increased tension, and some pain.

Eserine was instilled three times daily, with hypodermic injections of pilocarpine. The latter proving inoperative, the salicylate of sodium was administered in sufficient doses to cause free diaphoresis.

On January 27th all symptoms relieved.

On May 29th there was pain and augmented tension in the left eye, which had existed for three weeks.

Iridectomy was done at once, and completely relieved the symptoms.

Since this date he has returned, with increased tension in the right eye and some pain, which has been relieved by eserine.

CASE X.—Miss H., aged thirty-two, applied to me on September 19, 1890, with the right cornea so opaque as to only allow of perception of light. The projection showed perception of light 15° on the nasal side and 60° on the opposite side. There was some circumcorneal injection. In the upper portion of the iris, between the pupil and the periphery, was a small circular opening (coloboma). The tension was slightly increased and there was some pain. During two weeks a two-grain solution of eserine was instilled from two to six times daily. During two weeks the tension was normal or slightly increased. Paracentesis of the cornea was then done with temporary benefit. After one month a sclerotomy was done, which lowered the tension to the normal for three weeks. The cornea had cleared sufficiently for the patient to count fingers at sixteen inches. The nerve was now visible and found to show glaucomatous excavation. After three weeks the tension was increased, and eserine sufficed to reduce it to the normal, although it required to be used five or six times daily.

Six weeks from the performance of the sclerotomy, iridectomy was done. Since this time there has been only occasionally an increased tension, when eserine has reduced it to the normal. She then returned to her vocation of school-teaching, which she has continued to the present. I saw her in February, 1891, and the vision =  $\frac{20}{200}$  —. It seems to the writer very infrequent for the vision to increase from perception of light to  $\frac{20}{200}$  — in a case of chronic inflammatory glaucoma.

CASE XI.—N. W. A., aged fifty-five, applied to me on May 18, 1891. He had been rheumatic for several months. During six weeks he had had glaucomatous symptoms in the left eye. The eyeball showed considerable circumcorneal injection, with moderate pain and greatly augmented tension. Iridectomy was done at once.

Eserine was used. On the 23d the tension was normal, the injection of the eyeball much diminished, and the pain had disappeared. On entering the hospital there was only perception

of light on the nasal side, and on September 2d he could count fingers at six feet on the nasal side.

The vision of the right eye =  $\frac{2}{20}$ . On September 15th the tension was increased in the *right* eye. Eserine was ordered for both eyes.

October 24th.—Tension normal in both eyes, and vision perfect in the right eye; eserine still used in both eyes. The optic discs resemble those of glaucoma in the atrophic appearances, with the atrophic ring of glaucoma, but there is no abrupt peripheral excavation, except in the left there are a few bent vessels.

The patient is still under observation, and occasionally requires eserine to relieve pain and increased tension.

CASE XII.—Mrs. M. R., aged sixty, has had periodic pains in both eyes since three months, the right eye becoming first affected, and accompanied by periodic obscuration of vision. The nerves look atrophic, but not especially glaucomatous. The tension is increased in both eyes. The fields are somewhat limited.

The vision of the right =  $\frac{1}{60}$ , and the left =  $\frac{2}{100}$ .

February 3d.—A sclerotomy was done on the right eye. Eserine was used.

14th.—Tension normal, no pain.

18th.—Sclerotomy was done on the left eye.

March 4th.—The vision of the right eye =  $\frac{2}{60}$ , of the left eye =  $\frac{2}{100}$ .

11th.—Pain and increased tension in the left eye, which soon gave way to eserine.

April 8th.—There was pain and increased tension in the left eye, and an iridectomy was at once done, which completely relieved the symptoms. The vision in the right eye =  $\frac{2}{60}$ , and in the left =  $\frac{2}{60}$ ; whereas on entering, the right eye was =  $\frac{1}{60}$ , and the left was  $\frac{2}{100}$ .

CASE XIII.—Mrs. S. A. G., aged sixty-four, was admitted to the hospital on May 15, 1884, with severe pain in the right eye, which had been constant since three weeks. The left eye had more recently become painful. The sight was rapidly lowering. The pupil of the right eye was widely dilated and oval. Discs of both eyes atrophic, but having few glaucomatous characteristics. Both eyeballs injected. The vision of the right eye was perception of large objects; of the left, counted fingers at three inches on the nasal side. Iridectomy was done on both eyes on the day of admission.

Eight days afterward the tension was normal in the right eye, but increased in the left eye. There was no perception of light in the left, but the right eye counted fingers at two feet. There were hemorrhages into the anterior chamber of each eye. On the 29th the left eye counted fingers at fifteen feet, and the right at six inches. Discharged June 23d.

Dr. Reed Burns, of Honesdale, Pa., who referred her to me, writes that the vision of the left eye =  $\frac{6}{60}$ ; and again on July 16th, that the left eye is doing well but that the right is painful and becoming cataractous. The patient returned April 3, 1885, with the right pupil occluded, and calcareous changes in the cornea, with a red and painful globe. The left lens was becoming cataractous. The right eyeball was at once enucleated. The cataract in the left was not thought to be due to the iridectomy.

CASE XIV.—Washington L., aged forty-six. Ten years since he received a wound in the left eye from a bit of iron, which necessitated enucleation of the globe. Eight months ago the right eye exhibited symptoms of glaucoma. On entering the hospital the tension of the eyeball was increased, and the nerve showed glaucomatous cupping. The vision =  $\frac{6}{60}$ . Eserine was used with temporary benefit, but one week after admission it was found necessary to do an iridectomy. Eserine

was still continued. In one week the tension was normal, there was no more pain, the redness had nearly disappeared from the eyeball, and the vision =  $\frac{20}{20}$  +.

CASE XV.—Maggie W., aged twenty-two. This patient has had trachoma in both eyes for three years, and during the last month there has been great pain in the right eye and temple. The cornea is hazy and anæsthetic, the anterior chamber is shallow, and the eyeball too hard. Iridectomy was at once done, eserine being used. The tension was soon reduced to the normal and the pain was relieved. The patient counted fingers at one foot, whereas before the operation she counted fingers at four feet.

CASE XVI.—Joseph D., aged forty-three, has had gradual loss of vision since six months, without pain. The right eye was first affected, and is now the worse of the two. Both discs are deeply cupped. The pupils are moderately dilated, and the anterior chambers are shallow. The right eye has faint perception of light, and the left counts fingers at two feet. The field is limited and extends from 30° to 45° around the posterior pole. The tension is increased in each eye. A one-grain solution of eserine was used three times daily. In a week after the patient's entering the hospital Dr. Hepburn did a sclerotomy on the left eye, eserine being used in both eyes. Fourteen days afterward the tension was normal in each eye. On the next day sclerotomy was done on the right eye. Eserine was used in both eyes. Perception of light in the right eye was much improved. In the left eye the *field is nearly normal* and the vision =  $\frac{6}{60}$ .

September 16th.—The right eye counted fingers at eighteen inches.

30th.—There was increased tension in the left eye and eserine was used.

October 22d.—She was discharged with vision improved, but the field in the left had diminished to 70° by 20°, being about three times the original size.

CASE XVII.—Matthew R. R., aged fifty-four, has had symptoms of glaucoma simplex, dating back four years. There has been no pain. There has been occasionally a halo about the gas light. The fields are limited to about 20° in each eye. The tension was slightly increased and the pupils moderately dilated. The discs show glaucomatous excavation and appear atrophic. The vision =  $\frac{2}{100}$ . Iridectomy was done on both eyes at one sitting. The tension was reduced to the normal, but there was no change in the vision. Five years afterward there was no change.

CASE XVIII.—Mrs. T., aged fifty-seven, applied for treatment July 23, 1889. Six months since, she had a severe pain in the right eye and temple, lasting a day or two. Since this time she has had pain in the eye most of the time, except occasional intervals of four or five days. One month since, she noticed that the sight was lost and there was no perception of light. There was increased tension and glaucomatous excavation of the nerve. In the left eye the vision =  $\frac{2}{100}$ , the tension was slightly increased, and the nerve seemed to be physiologically excavated. Eserine was used in the right eye six times daily, and in two days the pupil was much contracted and the tension reduced to the normal. Did not return.

CASE XIX.—Mrs. B., aged forty-two, was first seen January 29, 1890. At the age of fourteen a door fell upon her head, wounding the left eye, and causing hemorrhage from the nose and ears. She has seen badly out of this eye ever since, but worse within two years. Since six months she has only perception of light. There are numerous punctate opacities of the cornea; the pupil is dilated, but responds slightly to light; there are lenticular opacities and floating bodies in the vitreous. The projection is imperfect; the nerve is so atrophic as to be

indistinctly located, but there is no excavation. The tension is slightly increased. The eye feels uncomfortable, but not positively painful. Eserine was used three times a day. The pupil promptly contracted and the tension soon became normal. The eserine caused some pain, and was discontinued for a short time.

December 20, 1891.—The patient again presented herself, saying that she had used the eserine daily ever since the last record.

The eye shows normal tension, is not painful, and is doing well. On November 2, 1891, the tension was increased, but the eye was in fairly good condition. Eserine has been used occasionally up to the present time and the eye is comfortable.

CASE XX.—Mrs. W. C., aged sixty, eight years since had rheumatism, which was accompanied by intense pain in the right eye. In a few days the sight of this eye was abolished. Since that time there have been occasional attacks of pain. Five years ago the sight of the left eye was foggy, but there was no pain. Three weeks ago it began to pain her, and the sight grew worse. The pupil is dilated and the anterior chamber is shallow; there is no sight. The right eye has a seral staphyloma, with a similar condition otherwise as in the left. Sclerotomy was at once done on the right eye and iridectomy on the left. In three weeks the patient was discharged, having no pain and with normal tension.

In all, there were twenty cases and thirty-two eyes.

Of these, there were four cases of *acute inflammatory glaucoma*, one eye only being affected.

Of *chronic inflammatory glaucoma* there were twelve cases and seventeen eyes. Of *glaucoma simplex* there were two cases and four eyes. There was one case and one eye with *hemorrhagic glaucoma*. There were four cases of *glaucoma absolutum*, with five eyes affected.

Of the cases of *acute inflammatory glaucoma*, Case I was completely relieved by iridectomy; the same of Case II. Case III was treated by eserine before and after sclerotomy, with vision improved from  $\frac{5}{c}$  to  $\frac{20}{xxx}$ . Case IV was relieved by eserine, leeches, and pilocarpine injections; vision not tested.

Of the cases of *chronic inflammatory glaucoma*, the right eye of Case V was completely relieved by iridectomy (vision  $\frac{20}{xxx}$  from counting fingers). The glaucoma was kept in abeyance for two years by occasional paracentesis of the cornea.

In Case VI iridectomy failed to relieve tension in each eye, and sclerotomy succeeded. In Case VII iridectomy relieved pain and tension, but did not affect the sight. The cornea was punctured by the keratome with great difficulty, although the instrument was in perfect order.

In Case VIII, right eye, pain and increased tension was relieved by eserine for more than a year; vision =  $\frac{20}{xxx}$  from first to the present time.

In Case IX both eyes were affected, on which paracentesis, sclerotomy, and iridectomy were done; eserine was used most of the time, even after the iridectomy, the last treatment being pilocarpine and salicylate of sodium.

In Case X the patient was treated with benefit by eserine, paracentesis, sclerotomy, and iridectomy.

Eserine was found to be of service even after the performance of iridectomy.

In Case XI, left eye, the sight was improved by iridec-

omy and eserine, from perception of light to counting fingers at six feet.

In Case XII neither nerve was excavated, but both were atrophic; sclerotomy permanently benefited the right eye, but iridectomy was needed in the left.

In Case XIII iridectomy was of temporary benefit to both eyes, but ultimately the left was enucleated and the right became cataractous.

In Case XIV the left eye was relieved by iridectomy and eserine. In Case XV iridectomy relieved tension, but lowered vision.

In Case XVI, of *glaucoma simplex*, sclerotomy and eserine relieved tension in each eye, improved the right eye from perception of light to counting fingers at eighteen inches, and in the left from fingers at two feet to  $\frac{20}{c}$ .

In Case XVII iridectomy relieved tension, but had no effect on the vision.

In *glaucoma absolutum* in the right eye of Case XVIII, the augmented tension was relieved by eserine.

In Case XIX, in the left eye, eserine has relieved augmented tension for two years, and so far has rendered an operation unnecessary.

In Case XX, increased tension in the right eye with some pain has been relieved by sclerotomy, and the left eye has been relieved by iridectomy. In the left eye of Case V iridectomy induced intra-ocular hemorrhage which necessitated enucleation.

*Eserine* was usually used in solutions of one grain to the ounce, but sometimes in two grain solutions, and as often, in some cases, as six times daily, without in a single instance causing iritis, and only occasionally inducing pain.

It has been found useful in acute inflammatory glaucoma, and in most of the cases of chronic inflammatory glaucoma, even before, during, or after operations.

In *glaucoma absolutum* it has succeeded often in relieving pain and augmented tension, and indefinitely warding off operations.

Paracentesis of the cornea has met with some success in temporarily relieving pain or increased tension in all forms of glaucoma, and seems to be free from danger.

## INTRACRANIAL NEURECTOMY OF THE SECOND AND THIRD DIVISIONS OF THE FIFTH NERVE.

A NEW METHOD.\*

BY FRANK HARTLEY, M. D.

In my experience, Mr. President, one of the most difficult instances in which the surgeon is called upon to decide upon the feasibility of further operative interference exists in recurrences of pain following neurectomies or neurotomies for persistent neuralgia. It is not always possible to determine whether the seat of pain is situated beyond the seat of the previous operation, whether a new painful branch still uncut sends by irradiation the feeling of pain in the

\* Read before the New York Surgical Society, January 13, 1892.

nerves operated on, or whether pressure or enlargement of the proximal end of the nerve is the cause of the recurrence.

With such uncertainty we can not be reasonably certain of a good prognosis until all branches of the trunk in which pain is present are cut.

In many of the operations for the relief of prosopalgia involving the second and third divisions of the fifth nerve, the difficult technique, the small field of operation, the arteries requiring ligature to preserve a clear field for the neurectomy, are important considerations. Especially is this the case where previous neurectomies have been done in the field of the operation. The history of the case which I wish to present this evening is as follows:

J. D., aged forty-six years, married, England, salesman, admitted to Roosevelt Hospital on August 8, 1891. The patient's father died of pleurisy; in other respects his family history is negative.

*Personal History.*—Patient denies rheumatism and syphilis. He has had malarial disease, but in other respects has been perfectly healthy.

In December, 1882, he was seized with a sharp neuralgic pain, at first referred to a spot about two inches to the left of the symphysis menti. This pain radiated over the whole left side of the face and head, involving the temporal region as far as the temporal ridge, and the left side of the tongue and mouth over the upper and lower jaws. The left orbit was involved in this attack.

This attack lasted eighteen hours, and, after an interval of four days during which time momentary attacks of pain were present in the same region, it reappeared. The second attack was more severe, and lasted two or three days. For the next two years he had constant pain over this region and was treated medicinally with aconite and morphine.

In September, 1884, the infra-orbital nerve, with Meckel's ganglion, was removed.

From the scars left, one would judge that either Wagner's or Chavasse's operation was performed at this time.

For four or five weeks he had partial relief. The constant pain disappeared, but the spasmodic twitchings continued. It soon reappeared, however, and the patient was again treated with aconite and morphine.

He had at this time thirty-one teeth drawn, thinking that the origin of the pain was located in them.

After eighteen months (1886), section of the inferior dental nerve was made by the same surgeon. The scars would lead one to think that Velpeau's operation was performed at this time.

On recovering from the ether he had an attack lasting seventeen days. From that time to the present he has had no change in his condition. The pain has been constant, except for an occasional period of one or two days. The contractions in the muscles of the face amount to forty in about thirty minutes.

Owing to the previous operations and the involvement of the lingual and auriculo-temporal nerves, I decided to attack the nerve at a point where I could divide the second and third divisions of the fifth nerve completely by one operation. The operation intended was to attack the nerve on the inner surface of the skull outside the dura mater, to isolate the second and third branches completely, to divide and resect as long a portion as possible. The advantages thought to exist in this method over Pancoast's, or its modifications by Krönlein, Credé, and Salzer, or Lücke's operation, were the easy access to the nerve, the comparatively large field for work, the rapidity with which the operation could be done, and the small amount of hæmorrhage.

The disadvantage was the inability to resect as long a piece as could be done in some of the other methods. This disadvantage I am certain can be overcome in the future when the knowledge of the degree of adhesion of the fifth nerve and dura mater is better appreciated. It is not difficult to go beyond the Gasserian ganglion.

This I did not appreciate fully before doing the operation on August 15, 1891. The operation performed was one in which an omega-shaped incision was made, having its base at the zygoma and measuring a distance marked by a line drawn from the external angular process of the frontal bone to the tragus of the ear.

The curved and rounded portion of this incision reached as high as the supratemporal ridge, the diameter of said circle being three inches. The skin and deeper tissues were cut in the shape of the Greek capital letter omega, a method of incision I first saw recommended by Uhle two or three years ago. This incision was carried down to the periosteum of the skull in all portions of the incision, except in the straight part at the base; the tissues were then retracted and the periosteum divided upon the bone in the same direction and as far as the straight part at the base.

With a chisel a groove was cut in the bone corresponding to the divided periosteum. This groove went to the vitreous plate, except at the upper angle over the rounded portion where it included the vitreous plate.

A periosteum elevator was here inserted and used as a lever to snap the bone on a line between the ends of the circular portion of the incision. In this way the breakage occurs along the lower portion of the wound, and a flap, consisting of skin, muscle, periosteum, and bone is thrown down, exposing the dura mater over a circular area of three inches in diameter. The middle meningeal artery was then tied, the dura mater was then separated from the bone, and the floor of the middle fossa of the skull was exposed. Broad retractors were used to raise the dura mater with the brain and to expose the foramen rotundum and the foramen ovale. The hæmorrhage was stopped by sponge pressure. The exposure of the first, second, and third divisions of the fifth nerve, together with the carotid artery and cavernous sinns, was exceedingly good.

The second and third divisions were isolated at the foramen rotundum and the foramen ovale, and, by slight pressure upon the dura mater, it could be stripped from the nerves to beyond the Gasserian ganglion. These were divided with a tenotome at the foramen rotundum and the foramen ovale, and that part between these and a point beyond the Gasserian ganglion was excised. As this amount of nerve is not very great, the ends of the nerves were pushed through the two foramina so as, if possible, to interfere with any reunion. In the retraction of the dura mater, owing to imperfect instruments, the third, fourth, and sixth nerves were somewhat injured. As no bleeding was present, the brain was allowed to fill the fossa. The flap—consisting of bone, periosteum, muscle, and skin—was replaced. The irregular edge of the vitreous plate which remained attached to the bone not involved in the flap acted as a shelf on which the flap rested and prevented its falling in upon the dura mater. The periosteum was stitched, the muscle sutured in place, and the skin sewn with silk. One drainage-tube was inserted at the lower angle; an antiseptic dressing was applied. Time of operation, one hour and forty minutes; the patient was carried to the ward in good condition. Following the operation, August 16th, ptosis of the left upper lid appeared, together with double vision and inability to move the eye. The patient was entirely free from pain and continued to do well for one week.

August 23d.—To-day a slight dermatitis appeared over the

area of operation, which is treated with ichthyol (ten per cent.) and bichloride irrigation.

On August 24th Dr. W. Vought examined the patient for me, and reported as follows: "The area of anæsthesia may be seen upon the shaded portion of the drawing. The other areas were the left side of the mucous membrane of the mouth over the upper and lower jaws, of the soft palate, of the anterior two thirds of the left side of the tongue, of the left conjunctiva and cornea, and of the left nostril. Muscular paralysis, complete, of the left buccinator, the pterygoids, and the left occipito-frontalis (frontal portion); almost complete, of all the external muscles of the eye. Ptosis; pupil normal. Nerves divided:

the second and third divisions of the fifth nerve, the branch of the seventh to the occipito-frontalis; injured, the third, fourth, and sixth nerves. The ophthalmoplegia externa I should give a fair prognosis for spontaneous recovery, as you will see by examining the patient that slight movement of all the eye muscles is present, which leads me to think the nerves have not been divided, but merely

severely injured. The ptosis could be corrected at any time."

*August 30th.*—Patient is to-day discharged cured and returned to the Vanderbilt Clinic, Nervous Department.

*September 30th.*—Patient has recovered from his paresis in the third nerve; the double vision, ptosis, and inability to use the third nerve have entirely disappeared. The paralysis of the pterygoids, temporal, and masseter muscles produced by the division of the motor portion of the fifth seems to have incommoded him to a very slight extent. The false teeth worn in the lower jaw before the operation fit quite accurately their opponents in the upper. Protraction and retraction of the lower jaw seem to be diminished, but elevation and depression of the lower jaw seem good. As the patient has chewed since 1882 all his food on the side opposite to the present paralysis, he has not been distressed by the division of the motor portion of the fifth.

The patient informs me that he is at present entirely free from pain and has gained in weight sixteen pounds.

I wish to say in conclusion that this method of reaching the base of the skull I have employed in the posterior fossa in a case of suppurative meningitis following otitis media. Though the case had a fatal issue, the exposure of the posterior fossa was good.

*January 13, 1892.*

**The Navy Register for 1892.**—The recently published Register of the Navy shows the following changes in the medical corps: The retirement of Medical Directors J. Y. Taylor and T. J. Turner resulted in the promotion of Medical Inspectors G. S. Beardsley and Henry M. Wells. These promotions and the retirement of Medical Inspector Theoron Woolverton have given a "step" to Surgeons Edward Kershner, J. R. Tryon, and W. H. Jones.

## A TOOTH-PLATE LODGED IN THE LOWER ŒSOPHAGUS MORE THAN A YEAR.

REMOVED BY EXTERNAL ŒSOPHAGOTOMY.\*

BY ROBERT ABBE, M. D.,  
SURGEON TO ST. LUKE'S HOSPITAL.

IN June last a man of thirty-five came under my care with a history of œsophageal stricture. He was emaciated and looked like a patient in the third stage of phthisis. He had been running down in health during the previous year, and of late had lost a pound daily. Attempts at swallowing produced severe coughing and gagging. A few spoonfuls of fluid could be got down at a time, but even that usually caused him to choke. More often a considerable part of what he swallowed regurgitated in a few minutes. He had been for three weeks under medical care in the hospital when he was transferred to my service. Not even the smallest œsophageal bougie could be got past the stricture, which was four inches below the cricoid. As this was an unusual site for a malignant growth, which it was thought to be, I asked the man if he had ever swallowed anything which might have stuck in his throat. He said "No." But on the following day he said that since I had asked him he remembered that on Decoration day the previous year he was intoxicated, and on coming to himself the next day found that he had lost his teeth and had a new set made at once. Some little trouble in swallowing made him visit a physician a day or two afterward, and during the next two months he visited two or three physicians, and finally entered a Philadelphia hospital. On all these occasions he expressed the fear that he might have swallowed the teeth, but, after repeated examinations with soft bougies, and being always told that nothing could be felt, he dismissed the matter from his mind, and was treated during the remainder of the year as a dyspeptic or consumptive.

Pain was never a prominent symptom, but the hard gagging, choking, and regurgitation of food, together with cough and progressive emaciation, made up the sum of his symptoms.

On hearing that he had possibly swallowed a hard substance, I at once passed into the throat a *metal* bougie à boule, and was gratified to feel the sharp click of the tooth-plate, which the soft gum-elastic bougies had never disclosed.

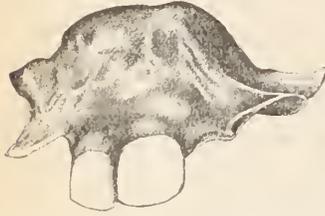

I regard that point as one of much importance in examinations of the œsophagus for foreign bodies. I was wholly unable to pass even the smallest bougie of any description beyond the obstruction. The bougie à boule was arrested between nine and ten inches from the incisor teeth.

On the following day I operated with the assistance of Dr. Murray.

Under anæsthesia the throat was palpated, to locate if possible the site of the obstruction, but nothing was to be felt. The usual three-inch incision was made as low as possible on the left side at the edge of the sterno-mastoid muscle. The omo-hyoid was divided and the superior thyreoid artery. The lobe of the thyreoid gland was found wrapped round the œsophagus quite well toward its posterior surface, and caused some delay in getting at the latter. Its arborescent surface vessels made a good guide to its recognition, as distinguished from the œsophagus, which was hidden from view by the thyreoid lateral lobe. A large, easily bent block-tin bougie was used through the mouth to make the œsophagus prominent. The latter I incised vertically for an inch and a quarter, and through this gap my finger felt the plate *an inch and a half below the suprasternal notch*. Loops of silk through the cut edges of the œsophagus held them

\* Read before the New York Surgical Society.

apart without damage during the extraction. A long curved dressing forceps soon removed it, with the aid of one finger of the other hand, which had to loosen each imbedded hooked end of the tooth-plate several times during its withdrawal.

The plate lay crossways with its concavity upward, the false teeth pointing forward. The œsophagus was

dilated into a fusiform pouch in which the plate could move. A large stomach tube was readily passed into the stomach after its removal.

Believing, as I said five years since before this society, that immediate suturing of the œsophagus was practicable and would give less trouble afterward, I used fine catgut to make continuous suture of the submucous and muscular coats of this tube; the external wound was tamponed lightly with iodoform gauze.

For the first day afterward nutrient enemata were given. During the second day sterilized milk was given through a small soft-rubber tube slipped well down the œsophagus.

The patient was greatly annoyed by copious secretions of laryngeal and salivary fluid.

During the third day a quart of sterilized milk was allowed the patient to swallow; nutrient enemata were also continued. The iodoform gauze tampon was replaced by a small drain tube.

For ten days boiled fluids were allowed to be drunk. The œsophagus incision healed primarily, and not a drop of fluid appeared in the neck.

The external part of the wound healed by granulation.

Soft solids were allowed on the eleventh day.

On the fifteenth day he was discharged, with the wound healed. He had gained steadily in weight, and was taking a full-sized œsophageal bougie.

Two months later the average-sized bougie was occasionally passed and he was improving.

## ON THE REDUCTION OF FEVER, PARTICULARLY IN TYPHOID.

### THE COMPARATIVE VALUE OF ANTIPYRETICS AND THE COLD-WATER TREATMENT.

BY LOUISE G. RABINOVITCH, B. S. (PARIS). M. D.

LATE RESIDENT PHYSICIAN, PHILADELPHIA HOSPITAL;  
ASSISTANT PHYSICIAN, INSANE ASYLUM, BLACKWELL'S ISLAND, N. Y.

It is hardly necessary to remind one of the differences of opinion as to the cause of fever. Most eminent authors differ as to whether it is due to increased production or decreased dissipation of heat. Any one who asks the question what fever is due to will find ample field for theorizing by reading MacAlister's comparison of fever as quoted by Dr. Isaac Ott in his work on *Modern Antipyretics*, which reads thus:

Suppose a tall vessel containing water, the level of the water representing temperature. Let two pipes be connected with this vessel, one conveying water, the other carrying it off. Let the inlet and exit tubes be each provided with a stop-cock, and let the two stop-cocks be connected by a rigid link which insures that they always turn together and by the same amount. If, to start with, the inflow and outflow are equal, then, however I move the linked stop-cocks, the height of the water will be the same. Now remove the rigid link, and connect the stop-cocks

by a spiral spring. If you move the inflow stop-cock so as to increase the inflow, the outflow one will not at once follow, and the balance being broken, the level of water will rise. But shortly the elasticity of the spring comes into activity, the outflow is equal to the inflow, and the rise will cease, but the new high level will be maintained. Every movement of either stop-cock will affect the level, which will fluctuate accordingly, but its height at any moment will not be an index of the amount of inflow at that time. The inflow may be slight while the level is high. If, now, you substitute heat production for inflow and heat dissipation for outflow, the rigid link will represent the healthy thermotaxic mechanism; then when this is weakened or relaxed or broken the steadiness of the normal level is impossible.

Dr. Isaac Ott, in his work on *Modern Antipyretics*, and Dr. William A. Carter, in his prize essay on *Heat Production and Heat Dissipation in the Normal and Febrile States*, have proved abundantly that temperature, heat production and heat dissipation are independent of each other, and that all are governed by special centers in the nervous system. Dr. Ott gives very convincing graphic tracings of his experiments, showing a case of induced septic fever where the heat production reaches its height some hours before the temperature curve, and the curve of heat dissipation is "lagging," as he styles it, behind that of heat production, although it follows it in its ascent. Another case was that where, after a starvation period, a high temperature took place while both heat production and dissipation had fallen below the normal. A third case was one of malarial disease, showing that heat production was at its height during the chill, that heat dissipation was not so great as at other times, and that after the fever had reached its height the previous rise was succeeded by an enormous fall of heat production; and it illustrated well how high temperature was not an index of the height of heat production. Heat dissipation is at its maximum during the stage of defervescence. He concludes by stating that the basal thermotaxic centers are the most important factors in the temperature phenomena of fever, and by his experiments urges the inference that the thermogenic, thermotaxic, and thermolytic centers are reflex in their activity.

In face of the enthusiasm of some physicians as to the use of the cold-bath treatment for reducing temperature, it is very convenient to stand by this statement. By reason of the intimate connection of the heat centers with the peripheral nerves, as has ably been shown in Dr. Ott's last work, the tonic influence of the water is conveyed to the thermic centers, which become again enabled to govern the body heat, whatever was the cause of disturbance of harmony between those centers.

Dr. Mary Putnam Jacobi reports a severe case of typhoid fever (*Times and Register*, 1890, p. 34) which was treated by cold baths. After the second day of treatment and the tenth day of the disease, the temperature reached its maximum, 106.2° F., and never reached that again; from 105° F. it was reduced to 98.8 by a cold bath, and it never reached any alarming degree till recovery took place, the latter having come at an earlier period than is usual even in a mild case.

The cold-bath treatment is contrafebrile and not antipy-

retic, Dr. Jacobi says, and she remarks that it is difficult to see, without serious reason, why the beneficial effect is brought about by diminishing the temperature  $2^{\circ}$  or  $3^{\circ}$  F. when the latter result always implies performance of work in and by the nervous system, which is already overtaxed by work. The question is very interesting. Perhaps it can be answered, if, as represented above, the thermogenic, thermotaxic, and thermolytic centers are intimately related in their action with the peripheral nerves. From Dr. Ott's standpoint, fever is due to lack of harmony between these centers, whatever may cause it. Fever does not necessarily imply either increased heat-production or diminished heat-dissipation, and it may manifest itself when both the latter are below the normal. Water acts as a sedative on those centers through the peripheral nerves, restoration of harmony between them follows, and pyrexia is reduced without involving the nervous system in the work for new production of heat.

To come nearer the subject of the cold-water treatment, Brandt advocates free nutritious feeding of the patient subjected to his method of treatment, in order to enable him to sustain the enormous drain of his vital forces; with this, and by strictly carrying out the rules which he gives for bathing a typhoid case, recovery must ensue.

Dr. L. Bouveret (*Lyon méd.*, 1891, lvi, 531, 565; lvii, 113) treated two hundred typhoid cases by Brandt's method, and says that it is his experience any antipyretic agents used with the cold-water treatment protracted the course of the disease. In one set of a hundred cases he had 7.5 per cent. of deaths, and in another hundred cases only 3 per cent., though some cases were of severe type. He corroborates Brandt's statement by saying that if a young patient dies of typhoid fever there was probably an imperfect point in the treatment; the patient was not treated by cold baths, was not bathed from the beginning, or was not bathed after Brandt's method.

Dr. J. E. Graham (*Canad. Pract.*, Toronto, 1891, xvi, 53-61) collected a large number of statistics on the subject and thinks that high temperature can always be controlled by cold sponging, and agrees with Dr. H. C. Wood that cold baths are much safer than are antipyretic drugs.

Antipyretic drugs in typhoid fever always remind the writer of this paper of a very severe case of typhoid fever in a girl, twelve years of age, who was admitted to the medical wards of Philadelphia Hospital.

She was nursing her mother in typhoid fever, and was taken ill with the same. She was cared for by a trained nurse at home. The temperature during her first day of illness (the day when she complained to the nurse of feeling sick) was  $103.8^{\circ}$ ; pulse, 100; respiration, 24. The temperature, pulse, and respiration were increasing progressively during the seven days of her illness at home. On admission to the hospital, her appearance was that of the severest type of typhoid fever. Temperature,  $104.4^{\circ}$ ; pulse, 102; respiration, 26. She was stupid and at times in active delirium. This condition continued throughout the period of her illness, and the temperature, pulse, and respiration were increasing progressively, with some fluctuations only, which were due to frequent doses of acetanilide (two grains at a time), or occasional sponging. There were no typhoid spots, and she had a soft, blowing, mitral regurgitant murmur.

From the seventh to the fifteenth day of her illness the temperature was between  $105^{\circ}$  and  $102^{\circ}$  F., with two exceptions ( $101.8^{\circ}$ ); on the fifteenth day reached  $99.8^{\circ}$  F., remained so for two hours, and ascended to  $103.4^{\circ}$ ; from the fifteenth to the eighteenth day remained between  $101^{\circ}$  and  $104^{\circ}$ ; fluctuated between  $100^{\circ}$  and  $105^{\circ}$  F. till the thirty-first day of her illness, when she died. The fluctuations were invariably caused by the frequent and repeated use of two-grain doses of acetanilide, which always reduced the temperature about  $2^{\circ}$  F., but the reduction was always of very short duration. The pulse was between 96 and 148, respiration between 24 and 60 a minute, throughout the course of the disease.

Several days after admission peculiar spots made their appearance on the body, apparently due to capillary embolæ. This view was held by all of the physicians who saw the case, and with the presence of the soft mitral regurgitation it was thought to be a case of typhoid complicated by septic endocarditis, the latter being the cause of the capillary emboli. On the twenty-ninth day of the disease the girl had a profuse intestinal hæmorrhage, she became more delirious than before, the hæmorrhages which followed were very large, from one to two pints at a time and too often repeated by day and night till the thirty-first day of the disease to give her a chance to recover.

The post-mortem examination revealed the most intensely engorged, infiltrated, and ulcerated lower bowel that the writer ever saw in the course of several hundred autopsies. There was no endocarditis, and no other pathological condition except profound anæmia of all the tissues and a very small cicatrix in a pulmonary apex.

Acetanilide affects the heart by depressing it profoundly; it causes cyanosis, and increases arterial tension. When a heart is beating at a rate of from 96 to 148 per minute it has already an immense amount of work to do. To depress such a heart and to increase the arterial tension seems really poor therapy. Had we used cold-water treatment the child would undoubtedly have made a good recovery.

In the subsequent cases of typhoid fever the writer never used antipyrine or acetanilide as an antipyretic. Cold water, either in the form of irrigation, cold pack, sponge bath, or plunge bath, was the stand-by as an antithermic. While in charge of the men's medical wards at Philadelphia Hospital the writer had under her care nine typhoid patients which included her own and Dr. S. M. Taylor's, who was sick at the same time. Three of them had pneumonia, and one left pleurisy with effusion, which extended to the third rib, and pericarditis with effusion; the heart was displaced almost entirely to the right, and for three days the cardiac sounds could not be heard, although the pulse was perceptible.

This case was of special interest. It was that of a young man, twenty-one years of age, tall and robust in appearance. He became delirious and violent and attempted to jump out of the window; his friends thought he was insane and sent for the ambulance. The physician diagnosed the case at once as one of typhoid and assigned him to the medical wards. On admission, he was in profound stupor and had a high temperature and rapid pulse and respirations. The plunge bath could not conveniently be used, but we gave him cold-water treatment by either irrigating him, keeping him in a wet pack, or sponging him almost every hour. Aside from the above-mentioned severe complications, he had intestinal hæmorrhages and double acute otitis media with perforation of both drums. He did well under the

atment. The effusion in the left chest and pericardium gradually disappeared, and he made a good recovery in a much shorter time than he would have under acetanilide treatment.

The three patients that had pneumonia were treated liberally by the cold water in whatever form it was most convenient regardless of that complication, and in no case was a cold bath administered without reducing the temperature at least two degrees. The patients always felt better, and usually enjoyed a long and refreshing sleep after it. All of the nine cases yielded well to the treatment, and at no time was there room for regret as to the use of the cold water.

In 1871 Dr. Wilson Fox (London) used the plunge bath liberally for reducing high rheumatic fever. He narrates two cases—one of a woman whose highest temperature was 109.1° F. and who had pericarditis as a complication; another, one of a man, whose highest temperature was 107.3° F. and who had double pneumonia, double pleurisy with effusion, and pericarditis with effusion. In this latter case the cold applications were at one time used continuously for eight days, and both cases made a good recovery. Dr. Wilson Fox remarks that the pulmonary and cardiac complications tend to resolution under this treatment.

There is a very excellent article On the Treatment of Typhoid Fever by Prolonged Immersion in Water (*Lancet*, 1890, pp. 633, 690), by Dr. James Barr. He has bathtubs in his hospital specially arranged so that the patient can remain in the bath for days, not to be removed until the temperature is reduced to the desired degree—100° to 99° F. He has treated all his cases by this method since accommodations were made for it, and records most fortunate results. The high temperature is broken up at an earlier time than with any other treatment; complications—such as intestinal ulceration, hæmorrhages, diarrhœa, etc.—make their invasion far less frequently than under any other treatment, and pulmonary and cardiac complications yield well to the same water treatment. The death-rate is much below that of ordinary antipyretic treatment.

The highest temperature the writer of this paper ever had to deal with was 109° F. It was in a case of puerperal septicæmia. The woman was delivered outside of the hospital, and, on her admission, pieces of membrane and placenta came out after the routine intra-uterine douche which is usually administered to women who come to the hospital after having been confined at home. It was a very alarming case. Quinine, acetanilide, antipyrine, cold sponging, and intra-uterine douches were used, but it never occurred to us to put the patient in a cold plunge bath, as she was a puerperal and not a medical patient. After a protracted illness the patient recovered; but any patient with marked fever that comes under my treatment hereafter, especially with a temperature of 109° F., whether of puerperal, rheumatic, or typhoid nature, will be put into a cold plunge bath.

Only recently I had a severe case of typhoid fever complicated by pneumonia and acute nephritis, the highest temperature reached being 106° F. Two grains of acetanilide were given in the morning; the patient became cyanosed, and her pulse was almost imperceptible for the following twelve hours.

A fatal case of acetanilide poisoning in typhoid fever is reported by Dr. Granville Macgowan (*Southern California Practitioner*, 1890, p. 379), and he now condemns entirely the use of antipyretic drugs in typhoid fever.

To conclude, the following tables may be found of interest:

*Vogl's Tables of 8,325 Cases, as quoted by Dr. Simon Baruch (Jour. of the Am. Med. Assoc., 1891, xvi, 369).*

	Combined treatment.	Pure bath treatment.
Mortality.....	6.7 per ct.	2.7 per ct.
Average hospital stay.....	40 days.	47.3 days.
Percentage of complications.....	102	65.2
Average daily number of stools for each person.	19	0.7

The following table is given by Dr. J. C. Wilson, of Philadelphia (*Medical News*, vol. lvii, 1890, p. 588), the cases of which treated at the German Hospital were his own:

Hospital.	Year.	Number of cases.	Average number of days in hospital.	Number of deaths.	Percent. of deaths.	Treatment.
Pennsylvania.	1889	31	38	5	16.1	Expectant.
Pennsylvania.	1890	46	37	6	13.4	Symptomatic.
Episcopal....	1889	69	44	9	13.04	Intestinal antiseptics.
Episcopal....	1890	40	51	5	12.5	Mixed internal and external antipyretics; no baths.
St. Agnes....	1889	19	36	2	10.5	Expectant-symptomatic.
St. Agnes....	1890	15	34	4	26.6	
German.....	1890	50	36.9	1	2	Ten of these were treated with carbolized iodine, and 40 strictly by cold baths.
German.....	1889	41	36.5	4	9.75	Expectant-symptomatic.

## A CASE OF CONGESTION OF THE LUNGS.

TREATMENT BY PHLEBOTOMY.

By H. W. VAN ALLEN, M. D.,  
SPRINGFIELD, MASS.

As the time of congestion of the lungs, pneumonia, and pleurisy is upon us, I am constrained to report the following case, especially for the benefit of the younger portion of the profession, some of whom, Hare justly fears, "would hardly know how to bleed if called to do so at a crisis." The case occurred at the Springfield Hospital during my service as house physician, and is reported that it may be an aid in bringing the profession to a more kindly feeling toward venesection:

A. A., aged nineteen years, single, Canadian, a laborer, of good previous health, employed at the hospital. He was thoroughly drenched in a rain storm during the evening of January 18, 1891. I saw him at 11 P. M., when he complained of nothing. At 7 A. M. the next day I was called to see him where he had been found in bed, gasping for breath, by another employee. He was removed to one of the wards for examination and treatment. His efforts were given so entirely to respiration that the subjective examination was limited. It was as follows: Severe pain over the heart, constant and cutting in character; cough absent; no expectoration. He said he had had a chill at

3 A. M. Objective examination: Temperature, 98.2° F.; pulse, 76, full and bounding in character; respirations, 52 a minute; nervous system unaffected. Examination of the chest: (a) Inspection: Form, normal; respiratory movements very labored and shallow and at times of the Cheyne-Stokes character; the apex-beat of the heart was in its normal place and very strong; the veins in the neck were pulsating. (b) Palpation: Vocal fremitus normal. (c) Percussion: No dullness; at least the same on each side. (d) Auscultation: Subcrepitant râles, especially over the left chest; vocal resonance normal.

Examination of the abdomen was negative.

The patient grew worse rapidly. In an hour the respirations at one time would reach 76 a minute and at others would cease entirely, so that it was needful to stroke the chest with a wet towel and use artificial respiration. Death seemed almost unavoidable. It was decided to do phlebotomy, and this was done by the attending physician, Dr. C. P. Hooker. The relief from the abstraction of four ounces of blood was almost immediate, as the patient thought he was entirely cured. He laughed with the attendants and complained of being hungry. Later, as his heart showed some signs of weakness, he was ordered ten grains of ammonium carbonate at hour intervals, but it was soon discontinued. The paroxysms of dyspnoea increased again in severity and frequency until it became needful to abstract four ounces more of blood, with a repetition of the former result. Later there was a return of the dyspnoea with lessened severity. Hypodermic injections of an eighth of a grain of morphine with one two-hundredth of a grain of atropine were given with good results. These were continued during the night.

During the next two days the dyspnoea gradually decreased. All physical explorations of chest were negative, and at no time did his temperature rise to 100° or his pulse to 90. A two-by-three-inch blister had been drawn over the heart.

On January 21st the patient began to expectorate large quantities of thin, bloody fluid. From this time he made an uninterrupted recovery, and was able to resume his usual occupation in a week from his time of admission.

**An International Periodical Congress of Gynecology and Obstetrics.**—The Belgian Society of Gynecology and Obstetrics, under the patronage of the Belgian Government, has taken the initiative in organizing the International Periodical Congress of Gynecology and Obstetrics, the first session of which will be held in Brussels, September 14 to 19 inclusive, 1892. Three leading questions will be offered for discussion: Pelvic Suppurations ("Referee," Dr. Paul Segond, of Paris); Extra-uterine Pregnancy ("Referee," Dr. A. Martin, of Berlin); and Placenta Prævia ("Referee," Dr. D. Berry Hart, of Edinburgh).

All communications pertaining to this congress should be mailed directly to the American secretary, Dr. F. Henrotin, 353 La Salle Avenue, Chicago, who will promptly furnish all information. All notifications to be forwarded should be received by August 1st.

**The Eleventh International Medical Congress.**—The congress that is to meet in Rome in 1893 has undergone preliminary organization by the election of Professor Guido Baccelli as president and Professor Edoardo Maragliano as secretary general. Communications, if not personal to the president, should be addressed to Professor E. Maragliano, Istituto di Clinica Medica, Ospedale Panmatone, Genoa, Italy. As at present arranged, the congress is to meet in September.

**Changes of Address.**—Dr. Robert H. M. Dawbarn, to No. 105 West Seventy-fourth Street; Dr. F. J. Leviscur, to No. 640 Madison Avenue; Dr. Max Rosenthal, to No. 130 East Eighty-second Street; Dr. Sebastian J. Wimmer, to No. 129 West Sixty-first Street.

**The Conviction of an Unlicensed Practitioner.**—Recorder Smyth has sentenced one Max S. Guggenheim to suffer two hundred days' imprisonment and to pay a fine of \$150 for practicing medicine without a license or a diploma.

THE

## NEW YORK MEDICAL JOURNAL,

*A Weekly Review of Medicine.*Published by  
D. APPLETON & Co.Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, MARCH 19, 1892.

## A BILL TO PREVENT THE ADULTERATION OF FOOD AND DRUGS.

THE United States Senate has just passed a law providing for the organization of a food section of the chemical division of the Department of Agriculture, having for its duty the analysis of foods and drugs offered for sale in any State or Territory other than that in which they are produced. The bill prohibits the introduction into any State or Territory from any other State or Territory or foreign country of any article of food or any drug that is adulterated or incorrectly branded; and violation of this provision is a misdemeanor punishable by a fine not exceeding two hundred dollars for the first offense and three hundred dollars for each subsequent offense, and by a year's imprisonment.

The term food is defined as including all articles, whether simple or compound, used as food or drink by man. The term drug includes all medicines for internal or external use; and they are considered to be adulterated when they differ from the standard of strength, purity, or quality recognized in the United States Pharmacopœia or other standard works, or when they are sold in imitation of or under the specific name of another article, or when they are mixed, colored, powdered, or stained so as to deceive the purchaser, or when poisonous or injurious ingredients have been added to them, or when, in the case of foods, the article consists in whole or in part of a diseased, filthy, decomposed, or putrid animal or vegetable substance, or of any portion of an animal that is unfit for food.

If the label or brand on the package containing the food or drug plainly indicates that it is a mixture, compound, combination, or blend, or if it is unavoidably mixed with some extraneous substance in the process of collection or preparation, or if a substance is added so as to fit the article for carriage or consumption, and not to increase the bulk fraudulently, it shall not be deemed to be adulterated.

The law further provides that the manufacturer or seller of any drug or article of food must furnish samples to the agents of the Secretary of Agriculture, and refusal to do this is punishable by a fine; also that these persons shall, in the case of adulteration, in addition to the fine, pay all the costs of inspection and analysis.

While this act will probably be opposed by those who deprecate the assumption of prerogatives of the States by the National Government, still it need not interfere with the exercise of police power by any State having existing laws relating to the adulteration of food and drugs. But, as so many of our States have no laws on this subject, and as the enactment of such laws is opposed by interested persons, and fails in con-

sequence of their opposition, the community at large must welcome this measure as calculated to further the welfare of its citizens.

#### WILL-TRAINING AS A THERAPEUTIC MEASURE.

EDUCATION as a preventive and cure of disease is a subject of special interest and wide import. To the strong education is a fortune; to the weak it is a necessity, like bread and air. Without it the weak easily become the vicious, the unbalanced, and sometimes the insane. The training of the will is the vital part of education. It has already effected remarkable results among the mentally deficient and among the insane. The work begun at the Bicêtre in Paris by the late Dr. Edward Seguin for the amelioration of idiotic children is now carried on with success by Bourneville and Sollier.

Teaching the insane is also an idea by no means new. From the Utica Asylum Dr. Brigham wrote of its great advantages in 1844, and classes were started there, but were shortly afterward abandoned. Similar brief experiments were tried by Dr. Earle and Dr. Kirkbride. In Dublin, however, superior energy and zeal, or some fortuitous circumstance, made it possible for Dr. Lalor to elaborate and carry out a scheme of education for the insane that for over thirty years has been attended with the happiest results. A paper in *The Popular Science Monthly* for September, by Dr. Charles W. Pilgrim, gives an account of the Richmond District Lunatic Asylum, the scene of Dr. Lalor's former labors, where nearly every patient, except those incapacitated in the hospital department, is engaged either in school or in industrial exercises, and about a fifth take part in both. The object of the school, as formulated by Dr. Lalor, is, first, to provide occupation for a large class who would otherwise be unemployed; secondly, to vary the occupation of the patients; thirdly, to apply a system of education to the relief of mental disorders; and, fourthly, to promote the happiness and welfare of all the inmates. Object-teaching prevails among the more stupid ones; reading, writing, arithmetic, and geography among those more advanced. Music occupies a most important place in this system. When the patient's attention can not be gained in any other way, it is possible to get him interested in the singing-class and afterward in other classes. Singing is accompanied by instrumental music, and even the theory of music is not neglected. Music naturally leads to drilling and marching. By placing the less active patients here and there in the line, even the most inert can be induced to take part in the exercises, and thus obtain an amount of physical training that it would be difficult to give them in any other way.

In this Irish asylum Dr. Pilgrim reports signs of activity everywhere, and a gratifying absence of the gloomy monotony that so often pervades asylum life. Here lives and flourishes a rational plan for the education, training, and uplifting of the insane, and for their health and happiness.

Three years ago, in the Utica Asylum, the earlier experiment of instruction was renewed. It is now in successful operation on a somewhat limited scale. Two patients who

could not read and write before becoming insane, learned to do both before returning home. One woman is the terror of the ward until ten o'clock in the morning, when she goes quietly to school, and for two hours is the most docile and interested pupil of all. Only fear of being kept away from classes makes her at all controllable at any other time. Is it unreasonable to hope that the day is not far distant when, in every well-organized hospital for the insane, a school will be considered one of the essential features in ministering to the mind diseased, since the training of the will is of first importance in all diseases of personality, in all conditions characterized by instability of the nervous system? This is a matter in which the life is more than meat, the body than raiment, and the human mind than any huge stone building, whatever its grandeur and architectural beauty. In the prevention and cure of disease education is the physician's most powerful ally, and one of the many duties of the modern doctor is to indicate the kind of mental and moral training best suited to individual needs.

#### LEPROSY IN BOGOTÁ.

From British consular reports some interesting information has been published regarding the prevalence of leprosy in the United States of Colombia. Although the first introduction of the disease probably dates back two hundred years, there has been no very rapid spread until within the last two decades. A medical monthly published at Bogotá by Dr. Pio Rengifo contains an estimate that of the one million population of the States of Santander and Boyaca, about one tenth, which would be a hundred thousand persons, are lepers. The lazarettos of these sections contain not far from 30,000 patients, according to the statement of a medical officer having charge of one of the largest of them. No actual enumeration has been made, and the reticence observed by the affected and their friends would militate against a systematic census, although there is very little dread among the people regarding the contagious aspect of the disease. The influence of the climate over it is stated to be peculiarly potent at certain localities having an elevation of 1,400 feet above tide-water. One such place, having a mean temperature of 82° F., is specified in the district of Tocaima, about fifty miles southwest from Bogotá, at a place called Agua de Dios. There is an asylum for lepers at that place, and there is a tradition extending back over a hundred years to the effect that the climate can stay the progress of leprosy. It has been asserted that lepers who went to that resort in good season, and remained there, have seldom died of leprosy, but from other causes. There are sulphur springs at the place which are resorted to by others than the lepers, but the latter do not use them. The different classes mingle together without restriction, and marriage of the leprous with the non-leprous is not uncommon. The offspring of these marriages generally show the effects by inheriting the disease or contracting it in childhood. Children of tender years are to be seen with well-marked leprous manifestations. The death-rate among the lepers is believed to be higher than among others.

Their stamina seems to be so far reduced that they fall easy victims to fevers, dysentery, and pulmonary troubles, although, if these diseases are eluded, the leprosy alone will spare them for a long term of years. One leper is said to have spent nearly forty years in the locality above named, and for the past eighteen years to have had very little pain or annoyance from his malady. As a rule, the people are callous and careless about the spread of the trouble, and seem to be averse to giving any attention to its repression. A species of fatalism seems to rule their thought, so that restraint and preventive legislation are not to be looked for among them.

#### GOUT OF THE PENIS.

SIR DYCE DUCKWORTH gave the clinical history of a case of gout of the penis before the Clinical Society of London on January 8th, as reported in the *Lancet*.

A man, forty-two years of age, a glass-cutter, was admitted into the hospital with gouty arthritis of several joints and moderate pyrexia. For about twenty years he had led a sedentary life and drank a quart of beer daily. Sixteen years before, he had had lead colic. He occasionally had suffered from attacks of articular gout, a disease which he had inherited from his father.

Five days before his admission into the hospital he was awakened by sudden pain in the right wrist and the right great toe joint. On the following day he awoke with pain in the penis and firm erection of the organ, which persisted. Three days later the left great toe joint was attacked with gout. The various thoracic and abdominal organs were found healthy. The urine was acid, of the specific gravity of 1.022, with no albumin. The penis was erect and tense, painful, and turgid. No points of hardness were found in its course. The testes were natural. There was no pain or swelling in the perinæum. The temperature varied from 99° to 102° F. Aperients and salines with colchicum were administered, and the patient was put on light diet. The priapism persisted uninfluenced by internal treatment, sedative suppositories, or lead and opium applied locally. A cage had to be placed over the abdomen to prevent contact of the penis with the bedclothes. Micturition was painful and the urine had to be drawn with soft catheters. From time to time fresh attacks occurred in various joints, but the priapism continued for twenty-one days without intermission, and then gradually subsided with the general amendment of all the symptoms.

The noteworthy points in this extremely rare case are the gouty inheritance, the sedentary habits, with exposure to lead poisoning, and the habitual drinking of beer.

#### MINOR PARAGRAPHS.

##### THE INCOMPLETE REMOVAL OF DISEASED OVARIES.

In the *British Medical Journal* for December 19th a brief note is given concerning conservative operations on the ovaries. At a meeting of the Surgical Society of Paris, Dr. Rontier stated his opposition to Pozzi's method of partial removal of

serelo-cystic ovaries. Conservative surgery, he holds, is inexpedient when the ovary is sclerosed, whether the tube is healthy or not. Pathological anatomy shows that in ovaries, under these conditions, all the ova have a tendency toward cystic degeneration. The stump left with a portion of the ovary on it is liable to a return of the disease, with all the attendant sufferings for the relief of which the original operation was undertaken. At the same time, the patient is just as surely sentenced to sterility as though the operation had been radical. The failure of the conservative operation has many times been due to an imperfect removal of one of the ovaries. Unsatisfactory results also have been due to the intentional non-removal of the Fallopian tube. The author has had experiences of this kind. In one case of hæmorrhagic metritis failure had followed the use of the eurette. He then removed the ovaries, leaving a healthy tube. But all the troubles returned and remained until the radical procedure of vaginal hysterectomy was performed. In two other cases, in women having retroflexion and metritis, the curette was successful in curing the flooding, but not the pain; hysteropexy was performed, but there were left unrecovered the almost healthy appendages on one side. A few months later he was compelled to do a vaginal hysterectomy. For these reasons Rontier has been led to abandon the temporizing policy of incomplete removal of the uterine annexa, even when they are in a sound condition, in the belief that he will thus often save time, trouble, and suffering to his patients. In the discussion following the paper, Pozzi replied that it was by no means certain that a woman would be sterile after the conservative operations on the ovary of the kind he had recommended.

##### THE KNEE-JERK IN THE CONDITION OF SUPERVENOSITY.

In a preliminary note in a recent number of the *British Medical Journal*, Dr. J. Hughlings Jackson reports the absence of the knee-jerk in some cases of emphysema with bronchitis in which the blood had become very venous, and also in a case of diphtheria in which tracheotomy was performed for dyspnoea producing cyanosis. When the cyanosis disappeared the knee-jerk could be elicited. At his suggestion Dr. R. Russell asphyxiated dogs by clamping the trachea, and found that the knee-jerk became exaggerated until knee-clonus was produced, but that in the third stage of asphyxia no reaction could be obtained. As asphyxia diminishes, and in an extreme degree annuls, the excitability of the motor cortex, the preliminary exaggeration of the jerk was probably due to loss of cerebral control over lumbar centers, which subsequently succumbed to the poisonous influence of supervenous blood. It is worth while, in all cases of apoplexy or coma, to note the degree of supervenosity, and to investigate, in regard to it, the state of the patients as to tendon reactions and superficial reflexes.

##### EPIDEMICS AND THE CONVULSIONS OF NATURE.

In *Le Progrès médical* for February 27th we find a paragraph recounting that an English gentleman, Mr. Harries, recently read before the Meteorological Society of the United Kingdom a paper on influenza in which he stated that epidemics of that disease generally coincided with volcanic eruptions, and suggested that volcanic dust from the depths of the earth, being suspended in the air after the eruption of a volcano, was the principal factor in the propagation of infectious diseases. The recent prevalence of influenza Mr. Harries is said to have attributed to an eruption of Krakatoa, in the Straits of Sunda, in 1883. If the date is given correctly, it must be remarked that a long period elapsed before the volcanic dust did its work. The general question of

the connection of epidemics with violent meteorological phenomena is not a new one, as those who feel an interest in it may learn—and at the same time be made acquainted with many curious facts and theories—by consulting a work on Epidemics written many years ago by our great lexicographer, Dr. Noah Webster.

A CURIOUS INJURY BY A STROKE OF LIGHTNING.

THERE is an account in the *Archives of Otology* for January of a case in which a man was struck by lightning on the left side of the head. It passed down the ear and along the neck and breast to the right arm, where it burned through the flesh, leaving the bone exposed, and then passed out into the metal work of the buggy in which he was seated. Some days afterward he applied to Dr. Clark for relief from an otorrhœa which had supervened, when it was found that the external ear and the meatus were burned superficially and the tympanic membrane ruptured, either by the direct stroke of the lightning or by the cauterization of the surface of the meatus, followed by supuration which afterward penetrated the middle ear. From the history and the appearances present the former hypothesis was considered the more probable.

THE CEREBRAL CORTEX AS A DRUG.

THE *Wiener klinische Wochenschrift* for February 25th contains an abstract of a communication made at a meeting of the Paris Academy of Medicine, held on February 16th, by Dr. Constantin Paul, from a report published in *La Semaine médicale*, 1892, No. 9. Dr. Paul spoke of decided benefit in cases of neurasthenic chlorosis, typical neurasthenia, persistent slowness of the pulse, and tabes dorsalis as the result of subcutaneous injections, of five cubic centimetres each, of a sterilized ten-per-cent. solution of the gray matter of the sheep's brain in the lumbar region. No untoward results are mentioned as having occurred even after numerous injections.

ASAFOETIDA AS A REMEDY FOR HABITUAL ABORTION.

THE *Centralblatt für Gynäkologie* for March 5th contains a summary of an article by Dr. Guido Turazza, of Padua, who gives his own testimony, together with that of several other Italian physicians, in favor of the efficacy of asafœtida as a preventive of abortion. A pill containing about a grain and a half of the drug is given once in two days at first, and gradually at longer intervals until finally one is given only every tenth day. The author regards asafœtida as a good remedy in the nervous derangements of women, and remarks incidentally that it has the advantage of regulating the action of the bowels.

CORNUTINE AS A PELVIC HEMOSTATIC.

IN the *Centralblatt für Chirurgie* for March 5th we find a brief abstract of an article by Dr. A. Meisels, published in the *Pester medicinisch-chirurgische Presse*, 1891, No. 39, on the use of cornutine in cases of hæmorrhage from the urinary and genital tracts, given in the amount of fifteen one-hundredths of a grain daily. The results are said to have been excellent.

FOOTBALL CASUALTIES.

THE *Lancet* continues to catalogue the results of rough play at football in England. In one of its latest issues five cases of injury are mentioned, in three of which death resulted. Rupture of the kidney and laceration of the intestines were among

the causes of death, as determined by inquest. One youth was dead within twenty-four hours after the receipt of his injuries.

ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending March 15, 1892:

DISEASES.	Week ending Mar. 8.		Week ending Mar. 15.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	20	3	4	12
Typhoid fever.....	8	4	7	2
Scarlet fever.....	219	38	231	31
Cerebro-spinal meningitis.....	2	4	0	0
Measles.....	337	21	328	20
Diphtheria.....	119	43	98	32
Small-pox.....	6	1	1	1
Erysipelas.....	0	0	0	0
Varicella.....	12	0	0	0
Pertussis.....	1	0	0	0
Mumps.....	2	0	0	0

**The New York Academy of Medicine.**—The order for the meeting of Thursday evening, the 17th inst., was a discussion on The Varieties of Pneumonia and their Treatment.

At the next meeting of the Section in Ophthalmology, on Monday evening, the 21st inst., a paper on Unilateral Albuminuric Retinitis and its Significance is to be read by Dr. W. B. Marple, and one entitled Remarks on the Pathology of Albuminuric Retinitis, by Dr. John E. Weeks.

At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 23d inst., Dr. Charles A. Powers will show a modified oral speculum, Dr. Beverley Robinson will read a paper on Diseases of the Upper Air Passages during and resulting from Influenza, and there will be a continued discussion on Hypertrophied Tonsils, with special reference to Methods of Treatment and the Question of Hæmorrhage after Excision.

At the next meeting of the Section in Obstetrics and Gynæcology, on Thursday evening, the 24th inst., Dr. F. Förster will read a paper entitled Clinical and Microscopical Analysis of Twenty-five Extirpated Ovaries, with special reference to Hæmatoma, and Dr. S. Marx will present one entitled A Case of Accidental Hæmorrhage during Labor, with Remarks.

**A Protest against the Baby Students' Relief Bill.**—At the regular meeting of the Section in Public Health and Legal Medicine of the New York Academy of Medicine, on Wednesday, March 16th, the following protest was unanimously adopted:

The Section in Public Health of the New York Academy of Medicine, whose membership comprises several hundred physicians of New York and Kings Counties, hereby earnestly protests against the passage of Assembly bill No. 513.

Its enactment would not only enable several hundred medical students to become licensed practitioners without passing the State medical examination, but also allow these students to be graduated after only two years of college study, instead of the three years' course prescribed by law. The members of this Section deem any such attempt opposed to enlightened public policy, which properly demands a guarantee from the State that a legalized practitioner of medicine shall be a competent one.

No lowering of the present standard of requirements for a license to practice medicine can be permitted without menacing the health of the people. Inasmuch as two graduating classes are already exempted (1891 and 1892), we believe no injustice is imposed upon the class of 1893 by requiring of its members the test of their qualifications required by the law of 1890, for every member of this class was matriculated with the full knowledge and expectation that he would have to pass these examinations.

In view of these facts, the honorable members of the Legislature from New York and Brooklyn are urged to oppose with vigor the passage of this proposed amendment.

**The Hospital Graduates' Club.**—At the next meeting, on Thursday, the 24th inst., Dr. W. E. Lambert will read a paper on Retinoscopy as a Method of estimating Astigmatism.

**The Brooklyn Surgical Society.**—The special order for the meeting of Thursday evening, the 17th inst., was the reading of a paper entitled A Report of Two Cases of Carcinoma of the Bladder, by Dr. H. W. Rand.

**The Medical Society of the State of North Carolina** will hold its thirty-ninth annual meeting in Wilmington on the 17th, 18th, and 19th of May. A debate on Puerperal Eclampsia will be opened by Dr. Frank W. Brown. After April 1st the address of the secretary, Dr. J. M. Hays, now living at Oxford, N. C., will be No. 826 Fourteenth Street, N. W., Washington, D. C.

**The German Poliklinik.**—Dr. Carl Beck has established a special department for surgical diseases of the neck.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 6 to February 12, 1892:*

WALES, PHILIP G., First Lieutenant and Assistant Surgeon, is relieved from further duty at Fort Apache, Arizona, and will report in person to the commanding officer, Fort Bowie, Arizona Territory, for duty at that station, relieving First Lieutenant William N. Suter, Assistant Surgeon.

SUTER, WILLIAM N., First Lieutenant and Assistant Surgeon, is granted leave of absence for four months, from March 22, 1892.

WOODHULL, ALFRED A., Major and Surgeon, having completed the duties assigned him by Par. 4, S. O. 303, A. G. O., December 30, 1891, will proceed from New York city to Hot Springs, Ark., and take station thereat as surgeon in charge of the Army and Navy General Hospital.

A board of medical officers, to consist of HUNTINGTON, DAVID L., Major and Surgeon; TERRILL, HENRY S., Captain and Assistant Surgeon; KILBOURNE, HENRY S., Captain and Assistant Surgeon; FISHER, WALTER W. R., Captain and Assistant Surgeon, is constituted to meet in New York city on the 1st day of April, 1892, or as soon thereafter as practicable, for the examination of candidates for admission to the Medical Corps of the Army.

By direction of the President, the retirement from active service this date, by operation of law, of NORRIS, BASIL, Colonel and Surgeon, is announced. War Department, Washington, March 9, 1892.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending March 12, 1892:*

BRATHWAITE, F. B., Assistant Surgeon. Detached from Hospital, Chelsea, and ordered to the U. S. Steamer Fern.

GATES, M. F., Assistant Surgeon. Detached from the U. S. Steamer Fern and granted two months' leave.

LAMOTTE, HENRY, Assistant Surgeon. Ordered to the U. S. Receiving Ship Vermont, at New York.

VON WEDEKIND, L. L., Assistant Surgeon. Detached from the U. S. Steamer Vermont and granted three months' leave.

KERSHNER, E., Medical Inspector. Orders to the U. S. Steamer San Francisco revoked.

VAN REYPEN, WILLIAM K., Medical Inspector. Detached as Assistant to Bureau of Medicine and Surgery and ordered to the U. S. Steamer San Francisco.

GATEWOOD, J. D., Passed Assistant Surgeon. Ordered to the U. S. Steamer Dolphin.

STITT, E. R., Assistant Surgeon. Ordered to the Naval Hospital, Philadelphia, Pa.

#### Society Meetings for the Coming Week:

MONDAY, *March 21st:* New York County Medical Association; New York Academy of Medicine (Section in Ophthalmology and Otolaryngology); Hartford, Conn., Medical Society; Chicago Medical Society

TUESDAY, *March 22d:* New York Academy of Medicine (Section in Laryngology and Rhinology); New York Dermatological Society;

Buffalo Obstetrical Society; Medical Society of the County of Lewis (quarterly), N. Y.

WEDNESDAY, *March 23d:* New York Surgical Society; New York Pathological Society; Metropolitan Medical Society (private); American Microscopical Society of the City of New York; Medical Society of the County of Albany; Philadelphia County Medical Society.

THURSDAY, *March 24th:* New York Academy of Medicine (Section in Obstetrics and Gynæcology); New York Orthopaedic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private).

FRIDAY, *March 25th:* Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

SATURDAY, *March 26th:* New York Medical and Surgical Society (private).

## Letters to the Editor.

### THE SPREAD OF SYPHILIS BY CIGARS.

23 WEST FIFTY-THIRD STREET, *March 7, 1892.*

*To the Editor of the New York Medical Journal:*

SIR: The two following cases may not be fitted to adorn a tale, but they certainly point a moral:

A cigar-finisher, aged nineteen, came to me on January 12th of this year with the following history: In the beginning of December of last year she noticed a swelling of the upper lip; a small lump appeared, which has continued to grow until it has attained its present size. About January 1st she noticed some blotches on the face and body, but these, she affirms, have disappeared. She gives an indefinite history of sore throat a month ago. She has grown thin and pale, and lost strength and appetite. She states that her friend, a girl who finishes cigars upon the machine next to hers, had a similar lump upon her lip three months ago, but is now well. She thinks she must have acquired some disease from her friend, since she used the same cup with her to drink tea at lunch. *Status præsens:* A pale and anæmic girl, undersized and rather stupid, has a typical hard chancre upon the upper lip, in the middle line; a general macular syphiloderm in full bloom on the face and body; diffuse specific pharyngitis; marked adenopathy; and moist papules on the labia and in the vagina, with a profuse discharge.

She has worked steadily up to the present time. She "finishes" the cigars made by a machine, biting off the ends of the wrappers and using her saliva to shape the tips. She maintains that it is absolutely necessary to finish them in that way; that even if a knife were used to cut off the redundant wrapper, the tip of the cigar must be shaped with the finger moistened at the lips. She has heard something of an order forbidding the biting off of the ends; but she states that every finisher in the factory—one of the largest in the city—does exactly the same as she does. She refused to believe in the contagiousness of her malady. She remained under treatment but a short time, and then withdrew from observation.

After much effort I finally saw her friend, who gave the following history: She was eighteen years old. On October 2d of last year a pimple appeared upon her lower lip, which grew to be as large as a nut. She gives a full history of syphilis—a general macular eruption, adenopathy, defluvium capillorum, rheumatic pains, pharyngitis, etc.

*Status præsens,* February 3, 1892: A tall, well-developed girl; stains left by roscola still visible on the chest and arms; adenopathy marked; large mucous patches on the tongue; on

the lower lip, a little to the right of the middle line, a small, pea-sized, distinctly indurated nodule.

She has been working steadily. She invariably finishes off the ends of the cigars with saliva, and says the practice is universal, as it would take too long to use knife and paste.

She has been under medical treatment, but professes not to have been warned of the nature of her malady. In fact, she refuses to believe that it is syphilis. She remained under treatment only a few days.

I certainly think that these are cases which are within the sphere of action of our public health authorities. I am not aware that any epidemics of syphilis have been distinctly traced to the use of cigars. It is possible that the tobacco leaf and tobacco juice in the mouth may render the contagious element innocuous. But it is also possible that the long period of incubation of syphilis has rendered it impossible to trace a source of contagion so unnoticeable. It remains a fact that upon every single cigar tip of the thousands finished by these two operatives there was probably deposited a portion of the virus of the disease. Moreover, the practice of using the teeth and saliva in the manufacture of an article which is destined to be taken into the mouth is not without serious objections entirely apart from considerations of disease.

It will probably be impossible in the future, as it has been in the past, to stop this unclean and dangerous method of cigar-making by pressure put on the operatives themselves. The saving time and trouble is so great as to outweigh every other consideration. All the influence of the French authorities could not induce the glass-blowers of that country to use the *embout*, or detachable mouth-piece, in their work, though the journeymen recognized its advantages; and Chassagny himself finally acknowledged with sorrow the absence of any practical result from his labors. But it is possible, I believe, to put the responsibility on the employers. They and their foremen must be aware of the methods used by their hands, and a sufficient penalty would, I am sure, secure an immediate reform. I commend the subject to the consideration of the Board of Health, and would suggest to smokers the use of cigar-holders in the interests of cleanliness, if of nothing else.

W. S. GOTTHEIL, M. D.

#### THE PRESERVATION OF HYPODERMIC-SYRINGE NEEDLES.

NORTH MANCHESTER, IND., February 29, 1892.

To the Editor of the *New York Medical Journal*:

SIR: Having noticed in various medical journals different plans of preserving hypodermic needles from rust or at least from occlusion, I have thought that a means that has been in use by myself for the last twelve or fifteen months might be of use to the profession generally. Accidentally I found that, if the needle head was filled with unguentum petrolei and then screwed on to the barrel, the needle would be filled with the ointment and perfectly preserved for an unlimited time. All that is necessary to do when you want to use the needle is to fill the barrel with water and force out the contents of the needle, or, in case you should forget to do so or are in a hurry, you may disregard the needle-filling and proceed with the injection, as no harm can come from the subcutaneous injection of so small an amount of ointment. I have used this method of preservation for small and large needles, have no use for the little brass plungers that accompany the needles, and have saved a great deal of time, possibly two or three lives, and quite a considerable amount of bad humor. If some one would construct a small bottle with a screw cap to which a small spoon was attached for filling the needle-head, to accompany hypodermic syringes, the outfit would be complete.

T. A. LANCASTER, M. D.

## Proceedings of Societies.

### AMERICAN LARYNGOLOGICAL ASSOCIATION.

*Thirteenth Annual Congress, held at Washington, on Tuesday, Wednesday, and Thursday, September 22, 23, and 24, 1891.*

The President, Dr. W. C. GLASGOW, of St. Louis, in the Chair.

(Continued from page 193.)

**Cyst of the Middle Turbinate Bone.**—Dr. C. H. KNIGHT of New York, read a paper with this title. (See page 309.)

Dr. WRIGHT: I am very much interested in the paper and specimens. Some years ago, after I had removed a bony growth from the middle turbinated bone, as a matter of routine, I decalcified it and made a number of sections of it. I was very much surprised to find that it had really contained a cyst; the contents were unfortunately not noted. The walls were entirely bony, and were covered with remains of a grunous material from the altered fluids. I could not distinguish an epithelial lining to the cavity; nothing but bone-cells. Shortly after, I read Schmiegelow's paper upon this subject; his explanation was that they are congenital. I wrote to Schmiegelow and inquired if he had found epithelium in these cysts, and he replied that he always had found epithelium in them. I had thought that possibly it was due to ordinary osteitis, causing hypertrophy, and then rarefying osteitis occurred with the formation of cysts; but, of course, if epithelium exists, the question is settled.

Dr. CASSELBERRY: Some years ago I made reference to a case of nasal myxoma which had apparently undergone calcareous degeneration. It was hollow, and formed of egg shell like substance, lined within by myxomatous tissue and without by the same, and also mucous membrane. It was so large as to totally occlude the nostril and push the septum far to the other side. It could not be removed entire, as it was brittle; it occupied the position of the middle turbinated body. After hearing this paper, I think that the explanation given of the mode of formation of cysts is probable, and that my case was originally an outgrowth of the middle turbinated body, followed by hypertrophy, and finally formation of a cyst.

Dr. KNIGHT: One of the most interesting points in cases of this kind is the character of the membrane lining the cyst. As represented in the drawing and as seen in the section under the microscope, it consists of columnar ciliated epithelium. As time passes and the lining membrane undergoes degenerative changes the cilia disappear, and in cysts of long duration we should not expect to find the epithelium preserved. The congenital theory sustained by Schmiegelow—which is substantially identical with the idea of Zuckerkandl—that the ethmoid cells may extend into the body of the bone, seems to me untenable for the reason that the lesion is not met with clinically in early life.

**A Case of Intrinsic Epithelioma of the Larynx.**—Dr. MORRIS J. ASCH, of New York, read a paper thus entitled. (See page 232.)

Dr. WRIGHT: I am especially interested in this case, because several months before the patient went to Dr. Asch he came to my office with his son. I can fully confirm the statement, made in the record, of the irritability of his larynx. It was only at a second sitting that I was able to see over the epiglottis at all. At that time there was very little to recognize; the larynx was simply covered with mucus, looking like chronic laryngitis. I told his son that in a man of his age, who had never had laryngeal trouble before, the outcome might be very serious.

Dr. ASCH: In addition to what I have said, I would like to

lay stress on the ease of performing tracheotomy with the aid of cocaine. The injection of a few drops of a two-per-cent. solution along the line of the proposed incision makes the operation absolutely painless. Another very interesting point in the case is that, a few weeks after the operation, the patient was attacked with a peculiar form of dyspnoea, coming on in spasmodic attacks. It was a spasmodic attack of this kind which occurred while he was on the boat where it was impossible to get medical assistance, together with weakness following an attack of the grip, that caused his death.

Dr. JARVIS: I should like to ask Dr. Asch why a secondary operation involving the larynx was not indicated in his case for the relief of the spasmodic attacks? Could he not have dissected out the carcinoma by performing thyrotomy?

Dr. ASCH: I suppose Dr. Jarvis refers to such an operation as Lennox Browne reports, where he opened the larynx and dissected out the cancer. In my case this could not be done, because in so old a patient the cartilage is too much ossified to permit of such an operation.

**A Case of Thyrotomy in a Child Eighteen Months of Age.**—Dr. CLINTON WAGNER, of New York, read a paper with this title. (See page 512, vol. liv.)

Dr. CLARENCE C. RICE: It would be exceedingly satisfactory, in the cases referred to in this very interesting paper, if the diagnosis could always be made before the operation is performed. I recall a case somewhat similar to the one reported, although the child was older (between three and four years of age), where I was able to make a diagnosis by the combined use of chloroform and cocaine. It is very difficult under ordinary circumstances to make a laryngoscopic examination in young children, and impossible to make the diagnosis of laryngeal obstruction without such examination. Before doing an external laryngeal section it is important to know the character of the occlusion, its location, size, etc. In making the laryngeal examination, the plan followed was to paint the posterior wall of the pharynx and fauces with a two-per-cent. cocaine solution, and to spray the larynx with the same; then I gave the child a few inhalations of chloroform while it was held upright in the arms of its father, and in this way I was able to make a satisfactory examination with the laryngeal mirror and to discover the multiple papilloma attached to the sides of the larynx, which were removed by endolaryngeal methods. In another case of apparent laryngeal obstruction in a child, seen within a few days, I was not able to make a satisfactory examination, and I intend using cocaine and chloroform in the manner described on my return. I think that by this method, which requires care and patience, we can make the exact diagnosis and can remove a growth or foreign body from the larynx in a case where a general surgeon would perform laryngotomy. In a case of a girl, five years old, in which I had the assistance of Dr. Joseph O'Dwyer, of New York, we removed several papillomatous growths from the larynx by the following method: The larynx was so thoroughly closed by these growths it was found necessary to introduce a tube and allow the patient to recover respiration before giving the anæsthetic. After slight anæsthesia was produced the tube was removed, the forceps was quickly introduced into the larynx, and as much of the growth as possible was removed before it again became necessary to introduce the O'Dwyer tube. The bleeding caused by the introduction of the forceps increased the dyspnoea. Both the forceps and the tube were carried into the larynx three times before enough of these numerous growths could be removed to allow the child to breathe without the tube. The growths returned, and a thyrotomy was eventually done. Two points I wish to make: (1) It is possible to make an examination in young children by the combined use of cocaine and chloroform, and (2) by the aid of

intubation we can introduce forceps into the occluded larynx of a child, and perhaps remove obstructions without opening the larynx.

Dr. J. C. MULHALL: There is one instrument much used by general surgeons which laryngologists should more frequently use; I refer to the index finger. The finger with its nail attached forms an instrument which may be very successful in removing papillomatous growths from the larynx. There is no difficulty whatever in reaching the larynx in young children, and with the aid of chloroform there should be no trouble in making the diagnosis. In one case that I recall I was enabled to effect a removal and a cure by the use of the finger-nail alone.

Dr. E. FLETCHER INGALLS: In examining young children, if the tongue is drawn well forward by a tongue depressor, like that devised by Mount Bleyer, we are often enabled to make a diagnosis by inspection. When the papilloma projects above the vocal cords it can often be detected by the finger. As the larynx is relatively high in children it can be reached without difficulty. I have several times detected papillomata in this way.

Dr. WAGNER: With regard to the use of ether or chloroform in these cases, I would say that for my own part I am afraid to give ether merely for diagnostic purposes, because of the danger of death by asphyxia. In three of the cases of children upon whom I operated I was compelled to perform rapid tracheotomy in order to avoid death on the table from asphyxia produced by the ether.

With regard to the use of cocaine in these cases, I might mention that my three cases previously reported occurred before the discovery of the drug. In one of them, that of a boy five years of age, I was enabled to make a thorough examination with the laryngoscope, and discovered a large papilloma, but in addition to the growth there was a membranous web stretching from cord to cord and probably more directly concerned in causing the dyspnoea than the growth; it was not possible to remove this membrane by the mouth.

In the case that forms the subject of my paper I think death from spasm of the glottis would have taken place had an attempt been made to make an examination with the mirror, either with or without cocaine.

(To be continued.)

## Reports on the Progress of Medicine.

### PÆDIATRICS.

By FLOYD M. CRANDALL, M. D.

**Common Errors and Fallacies in the Treatment of Children.**—Dr. Cheadle contributes an exceedingly interesting paper upon this subject to the *Practitioner* for July. One of the most common and dangerous errors is the belief so prevalent, both among physicians and the people at large, that a moderate amount of diarrhoea is beneficial. Upon this assumption a looseness of the bowels is often allowed to run unchecked until it has assumed dangerous proportions. It is not true that diarrhoea is a safeguard against convulsions. It is precisely those children whose vitality has been drained by diarrhoea and vomiting who are most liable to them. Young children bear purging badly, and the younger the child the greater the importance of getting a diarrhoea quickly under control. Nothing should be given as food that is not sterilized, and either predigested or easily digested. The author believes that opium is essential in severe cases even in young children, and that it is an error to withhold it. In later stages he believes the most efficient remedies bismuth in full doses and opium in small doses.

Night terrors is a most troublesome and at times alarming disorder, occurring, as a rule, between the second and sixth year. It usually occurs in delicate, sensitive, neurotic children. The direct source of irritation is frequently undue stimulation of the brain, as by exciting stories, rough and unkind treatment, overstudy, or some serious accident. By far the most common cause is constipation, often slight but persistent, the passages being hard, dry, and often light-colored. The point of error in the management of these cases is the use of mere sedative treatment. The neurotic element alone is recognized, and bromides are prescribed, often with good effects for a time. Unless the cause of irritation be discovered and removed, the bromides alone, while most valuable if properly used, will give but temporary relief.

Among the drugs most heedlessly used at the present day are antipyretics such as aconite, antipyrine, and acetanilide. Pyrexia is not the cause or essence of disease, but a symptom. The temptation, however, to reduce temperature when elevated above the normal is very strong, especially when it can be accomplished by the simple administration of a drug. It must be remembered that these are powerful agents having, in addition to their antipyretic power, other active properties. They are all powerful cardiac depressants. In most diseases marked by high temperature danger is to be apprehended from heart failure, not from pyrexia. That a high degree of fever is an element of danger can not be denied, but in no case is it the sole danger. This is true of pneumonia to a marked degree, and the results of antipyretic treatment in that disease have not been satisfactory. Children especially do not bear vigorous antipyretic treatment as well as adults. It is futile to attempt to cure the disorder that gives rise to a febrile state by the mere forcing down of temperature, and it is often extremely dangerous.

The cruel and useless practice of swabbing out the throat in diphtheria has nearly died out; but this method of applying astringents, antiseptics, and solvents still survives. After long observation of the effects of various methods of local treatment, the author has no hesitation in condemning as injurious the system of brushing out the throat. It is easy to do serious harm to the throat by such treatment and by abrading healthy surfaces to cause an extension of the membrane. It usually involves a severe struggle. The terror, excitement, heart strain, and physical exhaustion are most unfavorable conditions in a disease which tends to death by asthenia.

Other errors are the oppressive poulticing of the chest in pneumonia, which obstructs respiratory movement and tends to increase the body heat; the administration of emetics in diphtheritic croup, which is less effectual for good than for depressing the patient; their frequent repetition in bronchitis and whooping-cough, when there is no extreme mucous obstruction of the air passages to justify it; and the too free purging of rhaebitic children suffering from convulsions, under the belief that irritant matter in the alimentary canal is the sole cause of evil.

**Hydrocele in Infants.**—Sejournet (*Rev. mens. des mal. de l'enf.*, August, 1890) employs the term hydrocele in this paper because it suggests the idea of a collection of serous fluid in the tunica vaginalis, but, as it also implies the idea of being chronic, it is not as appropriate. As it appears in infants it is usually due to the extension of a cutaneous erythema. This red eruption about the buttocks is very common, and usually results from disordered digestion, the toxic materials contained in the fæces being the active cause. The author has seen this eruption advance gradually to the urethra, which it has evidently invaded, as shown by the pain and cries of the child during urination. This has been followed by tumefaction of the spermatic cord, and this in turn by hydrocele. He believes that all cases of acquired hydrocele follow this course. This disease is most common from fifteen days to six weeks after birth. It is always confined to one side, and has a peculiar tense but elastic feel, and is transparent by the light test. It is not a chronic affection, but passes away in from two to six weeks in most cases. It may remain after the erythema has been cured, and in rare instances becomes chronic, having all the characteristics of the disease as it appears in the adult. When it appears without a preceding erythema, as the author admits that it may, it is far more prone to become chronic. In treatment, the chief point is the improvement of the digestion by every possible means. Indigestion should, as far as possible,

be removed, and diarrhoea should be checked by restoring the digestive power. Erythema should be treated by the application of suitable powders or ointments. The hydrocele should be treated by astringent applications or by an iodide-of-potassium ointment.

**Prolapse of the Rectum in Children.**—Logan (*Liverpool Medical-Chirurgical Journal*, July, 1891) advises that the bowel before being returned should be washed with a strong solution of alum or dusted with tannic acid. In extreme cases reduction is difficult, but may be aided by the passage of a small rectal bougie. An anæsthetic may be required. The actual cautery is very effectual, or nitrate of silver may be applied in longitudinal lines, but in some cases wedge-shaped pieces of mucous membrane may have to be removed. For retaining the bowel in position the author employs a perforated celluloid tube four inches long and three eighths of an inch in diameter. It is retained in position by a flange at its lower end. In mild cases a pad and T-bandage may be applied with advantage.

**The Idiocy of Myxœdema.**—Bourneville contributes a series of interesting articles upon this subject to *Le Progrès médical*, vol. xii, Nos. 26 to 34, an abstract of which appears in the *Medical Chronicle* for December, 1891. The disease is known as cretinoid idiocy, cretinoid pachydermia, and sporadic cretinism. It is usually due to congenital absence of the thyroid gland. The exact relation of heredity in its production is uncertain. Alcoholism seems to have some influence, and it has been attributed by Down to intoxication of one or both parents at the time of conception. Tuberculosis and cancer would also seem to have an influence in the production of the disease. Insanity, hysteria, apoplexy, and migraine are often seen in the relatives of these patients. Females are more subject to the disease than males. The symptoms are rarely present until infancy is past.

These patients all bear a striking resemblance to one another, the symptoms being nearly identical in all cases. The intellectual development is interfered with and also that of the body, which shows profound alterations in the nutritive functions. The head is large behind, but low, narrow, and compressed in front, while the anterior fontanelle may persist for thirty years. The lower lip is everted, the mouth large, the tongue thick and protruding, the nose flattened, the cheeks swollen, the teeth imperfect, the chin small, the ears thickened. The neck is thick and short, with no trace of the thyroid gland. The belief that the primary cause of the disease lies in the absence of the thyroid gland is confirmed by the autopsy of myxœdematous adults in whom serious lesions of that organ are found; by the appearance of the symptoms of pachydermatous cachexy in individuals whose thyroid gland has been removed by operation; by the appearance of myxœdema in monkeys after thyroidectomy, according to Horsley's experiment; and by the absence of the disease if, during the operation of thyroidectomy in monkeys, a small portion of sheep's thyroid is implanted in the peritonæum, according to Schiff's experiment.

It is important to distinguish the idiocy of myxœdema from cretinism. In the following particulars they are similar: The face and body are hairless, the nose is flat, the lips are thick, the mouth is always gaping, the tongue is large and protruding, and the thorax is deformed. Both are thick-set and heavy and subject to rickets and scrofula.

In the idiocy of myxœdema the head is long, flattened from the forehead to the vertex, wide at the base, and square. The hair is coarse, rough, long, of brown or reddish color, with partial baldness. In cretinism the head is flattened from before backward, wide at the base, contracted at the vault, with no occipital protuberance. The hair is thick and abundant, and neither baldness nor white hair is ever found. In idiocy there is spurious œdema of the eyelids, cheeks, and ears. The ears are projecting and yellowish. There is no strabismus, retinal sensitiveness, or blepharitis. In cretinism there is true œdema of the lids with blepharitis. Strabismus is common and the retina is insensitive. In idiocy the saliva dribbles in infancy only, the lower lip is sometimes pendulous, and mastication is difficult. In cretinism the lower lip is pendulous, the saliva constantly dribbles from the mouth, and mastication is impossible. In this form of idiocy pseudo-lipomatous tumors are found in the supraclavicular regions, axilla, and sometimes in other regions. The neck is thick and short with no goitre; the breasts are absent and small. In cretinism there is goitre, but no

pseudo-lipomata. The neck is thick and short, and in true cretins the breasts are small, but in semi-cretins large and pendulous. In idiocy the genital organs are usually atrophied. In cretins they are rudimentary, but in semi-cretins often enormous. In idiocy the extremities are large, thick, and deformed. In cretins they are disproportionate, being either very short or very long, with deformed joints. The hands are large and thick, the feet large and flat with the toes overlapping one another. In idiocy the special senses are normal; the appetite is moderate with choice of food; the habits are cleanly. In cretinism the special senses are blunted, the appetite is voracious with no choice of food; the habits are filthy. Idiots of this class are modest; there is no onanism. The same is true of cretins, but in semi-cretins the direct opposite is seen. In idiots the movements are slow and the walk is difficult, but may be prolonged. Cretins are semi-paralytic and unable to walk. In idiots the vocabulary is limited as a rule, but is sometimes free. The voice is harsh and characteristic. Cretins are often mutes and never have a full vocabulary. The voice is normal.

The life of the idiots of myxœdema is short, but the condition is capable of amelioration. Treatment should be by tonic drugs and by all the pedagogical means usually employed in the education of idiots.

**A Case of Bromoform Poisoning.**—Sachs (*Contrib. f. klin. Med.*, Aug. 8, 1891) reports the case of a child, four years old, who took a gramme and a half of bromoform, the dose as prescribed being three drops. The child soon went into a state of collapse, the face being cyanotic, the extremities cold, and the pupils dilated. He was placed in a tepid bath and treated by injections of ether and rapidly recovered.

**A Case of Santonin Poisoning.**—J. A. Smith (*British Medical Journal*, June 6, 1891) reports a case of poisoning by a dose of three grains of santonin in a girl of three years and a half. The temperature was normal, the pulse 80, heart and lung sounds normal, pupils equal and slightly dilated, there being no diarrhœa, prostration, or eruption. She was said to have been delirious, but no true delirium could be noted. The majority of articles about the room were said by the child to be green like grass. While this was the predominant color, other colors were seen, but always false. Red appeared green; her mother's eyes, which were blue, were also called green. White was changed to yellow. Incontinence of urine occurred, the urine itself being of an intense saffron color, staining everything with which it came in contact. The symptoms subsided after a lapse of twelve hours.

**Vulvo-vaginal Inflammation in Children.**—Comby (*Bullet. et mêm. de la Soc. méd. des hôpît. de Paris*, July 23), in an excellent paper upon this subject, expresses the belief that the disease is rarely venereal in its origin. He reports one hundred and fifty-one cases, in eighty-four of which the patients were between the ages of two and ten years. The author has seen it in infants, but it is far more common in childhood and usually appears in the children of the poor, who occupy the same bed as older persons. While not gonorrhœal in character, it is in many instances contagious, and may result from a simple leucorrhœa. As the author has no belief in the gonococcus as a specific germ, this statement must perhaps be taken with reservation. The method of infection is readily explained in most cases. Clothing, handkerchiefs, and sponges soiled by leucorrhœal discharges of older persons may come in contact with the vulva of the child, especially when they occupy the same room or bed.

Besides the ordinary acute inflammation, the author has seen an aphthous variety associated with certain eruptions, especially chicken-pox and impetigo. In anæmic or strumous children it may assume a chronic form. It is also in some cases traumatic in its origin, and may be caused by irritation or injuries.

Of these varieties, the typical contagious form is the most persistent and least liable to disappear spontaneously. The treatment should be local and should consist of thorough cleansing of the parts twice a day with a warm solution of bichloride of mercury (1 in 2,000). A boric-acid solution, of the strength of four per cent., may also be used. The parts are then to be dried and dusted with salol and absorbent wool applied.

If the vagina is involved, a slender bougie or pencil composed of salol and cacao butter should be carefully passed through the hymeneal orifice. If the disease has assumed the chronic form, cod-liver oil and syrup of the iodide of iron should be prescribed.

**Intubation in Croup.**—Escherich (*Wien. klin. Woch.*, No. 7, No. 8, 1891), in considering the merits of tracheotomy and intubation, reaches the following conclusions:

1. Intubation can not in all cases replace tracheotomy.
2. Gross statistics do not properly show the actual value of intubation. Each case should be considered with regard to its peculiarities and the location of the disease.
3. The advantage of intubation is the ease and rapidity with which it may be performed, no anæsthetic and but few instruments being required, and no wound being left which will require treatment when the tube is removed.
4. The disadvantages are the ulcerations of the mucous membrane which are occasionally formed, the difficulties in feeding, the difficulty of removal of secretions and membranes, and the less perfect aeration of the lungs.

5. Tracheotomy is preferable to intubation when the membrane is extending rapidly into the bronchial tubes, or when the diphtheria is of an especially septic type. The same is true in weak children with slight respiratory power.

6. When the disease does not present special septic characters and the membrane is limited to the larynx, intubation should be performed.

7. After four or five days, if feeding becomes difficult and the membrane is extending into the bronchial tubes, the tube should be removed and tracheotomy should be performed.

**Jaundice in Children accompanied by Temporary Enlargement of the Liver.**—Enlargement of the liver is not generally regarded as of common occurrence in connection with simple jaundice. It is expressly stated by some authors that such enlargement does not occur. That this statement is erroneous is proved by twelve cases reported by Dr. Carpenter and Dr. Syers in the *Lancet* of September 12th. The authors believe that the condition, though frequently not recognized, is comparatively common. Several cases are reported in detail, all being unquestionably examples of simple catarrhal jaundice. They were all of the same character. Jaundice appeared in previously healthy children, lasted a few weeks and passed off, the liver in each case being more or less enlarged. In only a few had the enlargement wholly disappeared when the patient was lost sight of. In one instance the increase in size took place while the child was under observation. On September 23d the edge of the liver was felt an inch and a sixth below the costal margin and gradually descended until on October 31st it was two inches and a half below the ribs. These cases, unfortunately, throw no light on the causation of jaundice, neither is it apparent why the liver should be enlarged.

**The Treatment of Infantile Syphilis by the Subcutaneous Injection of Mercurial Salts.**—Moncorvo and Ferreira (*Revue mens. des mal. de l'enfance*, July, 1891) report a large number of cases of syphilis in young children treated by hypodermic injections of various salts of mercury. Of the soluble salts, corrosive sublimate is the best tolerated and most efficient. It is not proposed as the treatment for every case, but it offers a method to which we may turn with confidence if other methods fail. The following conclusions are drawn:

1. The value of the hypodermic method of treatment must be admitted.
2. Of the various salts, the corrosive chloride gave the best results as used with forty-seven children who received two hundred and fifty-nine injections.
3. The tolerance of this salt by very young children is perfect, and the effects are marked.
4. The injections should always be made with the most scrupulous antiseptic precautions. They may in some instances be repeated every four days.
5. The results obtained by means of mercurial injections are generally favorable, and the efficiency of the process does not seem to be inferior to that of other methods of administration.
6. The cutaneous lesions are more quickly influenced than the glandular.
7. As a rule, mercurials by hypodermic injection are well tolerated by young children, there being little tendency to salivation, stomatitis, and intestinal symptoms.

**Eucalyptus in the Treatment of Scarlet Fever.**—Bond (*Lancet*, June 6, 1891) reports forty-seven cases treated by oil of eucalyptus, both internally and as a spray or lotion for the throat. In view of certain glowing reports that have recently been made, the conclusions of the author are interesting. As a curative agent he believes it possesses no value, having no power to mitigate the severity or modify the course of the disease, and failing to prevent serious complications and sequelæ.

**Induration of the Sterno-mastoid in New-born Children.**—Dr. W. R. Parker, in the *British Medical Journal* of June 20, 1891, reports two cases which seem worthy of record on account of the infrequency of the complaint, its omission from most text-books on obstetrics, and its liability to be mistaken for inflammation of glands of the neck. The first patient was delivered artificially, some force being necessary in extracting the head. It was a dorso-anterior breech presentation. Twenty-six days afterward the child presented a marked induration about the middle of the right sterno-mastoid, drawing the chin over to the left shoulder. A few weeks' treatment with gentle frictions with a simple liniment resulted in a complete cure.

In the second case much force was also used in delivering the head, the breech being the presenting part. Twenty days afterward induration of the right sterno-mastoid appeared, sufficient to draw the head well over to the left shoulder. Six weeks' treatment was required for its removal.

In both cases there was doubtless sufficient force used in delivery to tear some fibers of the sterno-mastoid, causing inflammatory effusion and subsequently cicatricial contraction. In neither case was there the slightest suspicion of syphilis or other constitutional taint.

**Rickets in Australia.**—Dr. Muskett, in the *Australasian Medical Gazette* of July 15, 1891, says that in Australia rickets is a not uncommon disease, though it is the prevailing belief that it does not occur there. As the disease is described, the type is mild and the symptoms are not peculiar. It is interesting to observe that the disease is found by one who appreciates the symptoms and looks for them. The conditions favorable for the development of the disease are unquestionably present in Australia, and where such conditions are present the disease will certainly appear. As those conditions increase, as they are evidently doing in Australia, the disease will become more marked in character and more prevalent.

**Encephalocele.**—Broca (*Rev. des malad. de l'enfance*, June, 1891), in a paper upon this subject devoted chiefly to treatment, condemns pressure, puncture, and injections of iodine. Meningitis is the usual result of such operations, and when it does not occur the tumor rarely decreases in size. Incision leads to the danger of draining away of the cerebro-spinal fluid. Excision, with a ligature placed as low down at the base of the tumor as possible, offers the best promise of success. There is but little danger of removing brain substance, for the mass of the tumor is composed of other matter. As yet it is impossible to form an opinion as to the mental capacity of children who have been operated upon by excision.

**Laparotomy in an Infant.**—Schmidt (*Deuts. med. Woch.*, xii, 1891) reports a laparotomy in a child, six months old, for the removal of a tumor. It proved to be a sarcoma of the kidney and was the size of an infant's head. A complete recovery followed in three weeks. In cases of this character examination of the urine often fails to give any assistance in diagnosis. Renal tumors are far less movable than those of the spleen.

**Aprosexia and Headache in School Children.**—Dr. Guye, of Amsterdam, presents another contribution upon this subject in the September number of the *Practitioner*. This term was applied by him several years ago to the condition marked by feebleness of memory, headache, and inability to fix the attention on any abstract subject, seen in certain children suffering from disease of the nose and nasopharynx. Relief of such nasal disease is quickly followed by marked improvement in the mental condition. These children are always mouth-breathers, they have a dull, stupid look, and often suffer from headache, which is usually constant and persistent. The mental condition is explained by the fact that the abnormal growths obstruct the cerebral circulation, especially the lymphatic. Attention is drawn to

the importance of mouth-breathing as a symptom, especially in children who remain backward in intellectual development.

**A Case of Myositis Ossificans.**—Macdonald reports a remarkable case in the *British Medical Journal* of August 29th. The patient was a girl four years old, brought for treatment because of inability to raise the arms from the sides. This was found to be due to a semi-ossified condition of the muscles surrounding the shoulder joints. The muscles of the neck were also becoming ossified, the sterno-mastoid of the right side standing out like a rod of iron. There were also nodes scattered over the head, scapula, spines of the vertebrae, ribs, and sacrum. These nodes appeared and disappeared and seemed to be influenced by treatment and were strongly suggestive of syphilitic taint. But no other evidence of that disease could be obtained either in patient or parents. There was no suspicion of rheumatism. The condition was first observed when the child was two years old.

Treatment seemed to have no effect except upon some of the nodes. An attempt was made to gain more motion by removal of the bony material from the tendons of some of the muscles. Though the incisions healed readily, the results were not satisfactory.

## Miscellany.

**A British View of American Surgery.**—Mr. Rutherford Morison, who says he has recently spent eighteen days in America, has contributed to the March number of the *Edinburgh Medical Journal* an article in which he says:

In crossing the Atlantic I was fortunate in meeting Dr. Draper, physician to Roosevelt Hospital, New York, and Dr. Kelly, gynecologist to the Johns Hopkins Hospital at Baltimore, who were returning after a holiday in Europe. Armed with introductions from these gentlemen, I was enabled in a short time to see a good deal of surgical work, and met with a very agreeable reception. An introduction is, however, not essential. The American surgeon is a good fellow, and it will be a Britisher's own fault if he can not get along with him.

I arrived too late to attend the Washington Medical Congress, where the attendance of several distinguished British surgeons (Professor Chiene among them) at the meetings was much appreciated.

The first hospital I visited was the Roosevelt, in New York, with about 250 beds. This hospital is an excellent one, but cramped for ground space, and not built in accordance with the latest views on hospital construction. It will soon, however—for the building is nearly completed—be possessed of the finest operating theatre in the world, erected at a cost of £80,000. The sum was left by a wealthy benefactor, with the express stipulation that the whole of it should be expended on this object. The area is to be wholly marble, and the difficulty of disposing of so much money is being met satisfactorily by making it quite an extensive building. There are to be isolated ward-rooms at the top; the operating room, porter, and nurse are to have quarters there. Photographic, bacteriological, and pathological rooms are to be provided, and a number of special rooms are to be set apart for instrument sterilizing, and disinfecting apparatus, dressings, and the special appliances for preparing them, and consulting and other rooms for the staff.

In the hospital, among several interesting cases, I noticed a boy who had recovered after an operation for perforating ulcer of the vermiform appendix with general peritonitis. The abdomen had been opened and cleansed and the vermiform appendix removed by Dr. Hartley. This was the only case known to have recovered after such a lesion in New York.

Another youth was recovering after an operation for intestinal obstruction, due to a band and adhesions; and the interesting feature in his case was that a year before he had been laparotomized for tubercular peritonitis.

Dr. McBurney had several cases on which he had performed an operation of his own for the radical cure of hernia. He ligatures the sac at its neck, removes it, slits up the whole length of the canal and

the skin covering it, sutures the upper skin margin to the conjoined tendon, the lower to Poupert's ligament, draws the inverted skin margins toward each other by deep sutures, and packs the resulting ditch with dressing, from the bottom, till the wound is healed. The object is to secure a firm fibrous barrier against the descent of another hernia. The large gash, held by button sutures, looks formidable, but the results are said to be excellent; and I had the opportunity of examining a young man who turned up three months after operation, meanwhile having been at work, and in him the site of operation appeared to be much the strongest and most resistant part of a strong abdominal wall.

The genito-urinary cases are kept in a separate ward, and have male attendants. A considerable number of buboes were under treatment during my visit; and, judging by what I saw, I think it would be fair to assume that bubo in America must be a much more serious disease than with us. It is the rule to dissect out all the infected glands, and to remove all infiltrated skin. The result necessarily is, in some cases, a huge granulating surface in the groin. One man I saw had had the misfortune to have the glands and skin on both sides affected, and when seen by me, had a granulating area on each side quite the size of my outspread hand. The same treatment was adopted in Vienna when I was a student there in 1878.

There were several cases of urethral stricture under treatment, and I was surprised to learn that all strictures are dealt with by internal urethrotomy. Those in the penile portion are cut only; those behind are cut, and in addition the bladder is drained through the perinæum. Dr. McBurney has invented an ingenious instrument for making a small perineal opening just large enough to admit a drainage-tube, instead of the larger incision necessary when the bladder is drained in the ordinary way.

The bougies used in the after-treatment are terrible-looking weapons, and "bougie day" did not appear to be anticipated by the patients with feelings of unmixed satisfaction. Surgical principles are not elastic enough to allow of such a radical difference of opinion and practice as I saw there and see with us. If they are right we are wrong.

I had the opportunity of examining some cases recovered after operations for the removal of malignant growths. The operative treatment adopted is much more radical than is the rule with us—*e. g.*, in an ordinary case of scirrhus of the mamma it is usual to remove a large area of skin covering and surrounding the growth, to take away the pectoralis major, divide the pectoralis minor, and dissect out from the axilla everything except vessels and nerves. The skin gap is filled up by a Thielsch's graft—an excellent method, not sufficiently used here. I had the opportunity of seeing that the usefulness of the arm was but little impaired by the loss of the pectoralis major.

In cancer of the tongue an incision is made through the center of the lower lip, down through the middle line of the chin and neck to the hyoid bone. A second incision crosses this, running along the lower edge of the body of the jaw from one facial artery to the opposite. The flaps so marked out under the chin are reflected, the glands dissected out, and the lingual arteries tied. The lower jaw is now sawn through in the middle line, and the floor of the mouth and tongue removed. In one case, I think a patient of Dr. Halsted's, of Baltimore, the upper part of the larynx and a considerable portion of the pharynx had been removed in addition, and a year after the patient was in excellent condition and free from recurrence.

In all operations the most strict aseptic and antiseptic precautions were used, here as in all other hospitals I visited; the operator, his assistants, and the operation-room nurse, all wore special clothing; but I will enter more fully into detail on this point later in connection with the Johns Hopkins Hospital at Baltimore.

Ether was the invariable anæsthetic. It was administered on a simple stiff cone covered by a towel. At Boston it was given on a large, thick, cone-shaped sponge, without accessories of any sort—a safe, efficacious, cleanly, and simple method. Chloroform is mostly regarded as unsafe, and ether is in general use.

The catgut for ligatures was prepared here in a simple way. It looked well, and was said to be satisfactory when tested clinically and bacteriologically. The gut, bought dry and unprepared, was first put into ether from two to four hours, depending upon its thickness, then into 1-to-1,000 corrosive lotion for the same time, and from this into

alcohol, where it was permanently kept till required for use. All instruments were sterilized before use in a special hot-air or steam sterilizer.

Iliadorn's needle and needle-holder were used for the introduction of sutures, and a needle-holder had two arguments in its favor—first, convenience; and, second, it was more readily and surely sterilized than fingers. A large number of sutures were used in wounds. Tier upon tier of catgut sutures held the deeper structures in apposition until the sides of the wound were so closely opposed that there was no space for and no need of drainage. Cheap sponges, made use of only once, were employed during operation. The dressings were gutta-percha protective dipped in weak corrosive lotion, and torn into small patches, next the wound, and either sterilized gauze and wool, or corrosive gauze and wool heaped outside of this and retained by an ordinary roller bandage.

*Bellevue.*—Bellevue is an old-fashioned large hospital (eight hundred beds), with a medical school in its grounds. There I saw a laparotomy performed by Dr. Polk, gynecologist to the hospital. The operating theatre is a very large one, much resembling the theatre of the old Edinburgh Infirmary in its arrangements and appearance. From one hundred and fifty to two hundred students were present, and waited comparatively quietly for Dr. Polk and the patient.

On Dr. Polk's arrival he was greeted with enthusiastic cheers, for he had just returned from a holiday in Europe. The patient was immediately wheeled in on a couch, under the influence of ether, and her case briefly discussed. She was then stripped and placed on a low, short operating table, only long enough to hold her body. The legs rested on a stool. The operator explained that he had brought her unprepared to show the methods adopted preliminary to operating, and an assistant proceeded to smear the abdomen with an alcoholic solution of soap, and with the vigorous use of a nail-brush and hot water soon produced an abundant lather. The pubis was now shaved with a razor and the lather washed off by pouring a hot solution of corrosive sublimate from a jug over the abdomen. While the abdomen was being attended to by one assistant, a second was cleansing the vulval orifice and interior of the vagina by directing the flow of lotion over and into these parts by his hand and fingers. The cleansing process finished, the patient was entirely covered by antiseptic moist towels, excepting a portion of the abdominal wall of parallelogram shape, reaching from the umbilicus to the pubis. Dr. Polk and his assistants, having thoroughly washed and disinfected, got into their respective places. The former seated himself at the lower end of the table, between the thighs of the patient, with a leg on either side of him, and his abdomen resting against the patient's perinæum. This, he said, was Martin's (Berlin) position, and had many advantages. An assistant stood on each side of the patient ready to help the operator. A variety of matters were discussed and explained during the proceedings, and an occasional halt made when any particular point required emphasizing. The operator, taking a long-bladed bistoury, and commencing the incision just below the umbilicus, with one skillful sweep cut through all the structures at once, down to either fascia transversalis or peritonæum, for the next step was to seize the tissues at the bottom of the wound on either side with two pairs of artery forceps, between which a nick was made, opening the peritonæum. The finger was now introduced and the peritonæum slit up the length of the wound. The uterus and appendages were then drawn forward, the extent of disease, a double hydrosalpinx, ascertained, and the operation completed by the removal of the diseased appendages in the most approved fashion.

I have not yet shaken off a feeling of being in sacred ground when my hand is in the peritoneal cavity, and it was somewhat startling to me to see the unceremonious way in which this operation was performed at Bellevue. The impression conveyed to my mind was that the operation was as exciting to the operator as the operation of trimming the nails is to an ordinary mortal, who is occupied in conversation while doing it, and does not feel the least need of hurrying over the performance.

I have never seen an operation more skillfully performed; but the advantages of the position adopted would have to be very clear before a British surgeon could be persuaded to adopt it. It is not an elegant one.

*The New York Hospital.*—This is a very handsome building, outside

and in. It is built on the pavilion principle, and each individual ward is a model of what a perfect hospital ward should be. Unfortunately, it has been built on a limited space, and is five stories high, with a very limited interval between each block. The consequence is that the natural lighting and ventilation of the lower wards especially is considerably interfered with.

Dr. Weir, one of the surgeons to the hospital, kindly conducted me round, and I had the opportunity, after the visit, of seeing Dr. L. A. Stimson excise the vermiform appendix for perforating ulcer and peritonitis. The patient was a young man of about eighteen, who, six months before, had an attack of perityphlitis, from which he recovered under medical treatment. He was now suffering from a relapse, with urgent symptoms, and though his abdomen was much swollen and tender, a large resisting mass could be felt in his right iliac fossa. An incision about six inches long was made in the right linea semilunaris, and a quantity of fetid pus welled up as soon as the peritonæum was opened. On further opening the peritonæum it was seen that the pus was well localized and shut in by adherent coils of intestine, with the exception of a small place at the upper part, where a communication might possibly exist with the general peritoneal cavity. The pus was very carefully sponged out with small sponges in long forceps, wrung out of 1-to-1,000 corrosive lotion, particular care being taken not to disturb any of the adhesions toward the cavity of the abdomen. The vermiform appendix was then seen projecting from the end of the cæcum into the cavity, like a thick reddened spur, and after tying and dividing its mesentery it was ligatured at its base and removed close to the cæcum. The exposed interior of the divided appendix was then touched with pure carbolic acid, and afterward seared with the point of a thermo-cautery. When all blood and pus had been cleared away by sponging, the pus cavity was gently packed with strips of iodoform gauze all round the stump of the appendix. The wound was sutured and the ends of the gauze strips left projecting through a small gap, to be taken away later, when further adhesion had made it safe to do so.

To see this operation was a great treat. The consummate skill with which it was performed, the careful attention to every detail in the performance, and the scientific way in which possible accidents were provided for, insured success, if success was possible.

The appendix was opened in my presence, and there was, near the end, an ulcer about the size of a threepenny bit, which had perforated near its center at one very minute point.

During my visit I saw at least five cases in which the appendix had been removed for similar conditions. The only deduction I can make is that appendicitis is more common in America than in Europe.

When discussing the condition with Dr. Hartley, surgeon to Bellevue Hospital, I mentioned that in three cases, at least, I had opened a perityphlitic abscess with good result, immediate and remote, so far as I knew. He said the appendix was always removed in America in such conditions when it was possible to find it, as, if it was not, relapse was not infrequent. In proof of his statement he showed me a boy whose appendix had been removed a few days before, and his history was that a few months ago an abscess had been opened after a severe illness, and healed; he got quite well, had a relapse, and had now been admitted a second time with recurrence of similar symptoms, and had his diseased appendix excised.

The *Johns Hopkins Hospital* at Baltimore, on its completion, will be the most perfect large hospital in the world. It will be double its present size, and will then have four hundred beds. Possibly this statement may give the impression that it appears unfinished at present. This is not the case. Everything, so far as it goes, is complete, and everything that medical or surgical brain could wish for and think of is there. The appointments on the staff are the best in all America, for they secure to their fortunate possessors an income of £1,000 a year, with no restrictions whatever. Could any conditions be better calculated to secure for the citizens of Baltimore the best medical services?

Dr. Hurd, superintendent of the hospital, showed me round. He had the whole working of the hospital at his finger ends, and appeared to know all that was going on equally well in every department—medical, surgical, gynecological, pathological, and bacteriological. He knew every instrument, recent and late, and could explain its advantages and disadvantages; every dressing, new and old, he had considered, and

what things were necessary, good, and indifferent in the hospital he was clear in pointing out.

The out-patient department was the most perfect working arrangement I have seen. No time was lost, and with very little trouble a good record of each case was kept.

There is a good opportunity at Baltimore, as at Liverpool, of comparing the circular ward (or more correctly at Baltimore, octagonal) with pavilion wards, as each hospital has wards on both systems. I could get no expression of opinion at either Baltimore or Liverpool as to which was considered best, except that Dr. Hurd told me that patients preferred the circular, as feeling more private, from the central pillar hiding one third of the ward from the remaining two thirds, and that nurses liked the ordinary ward best for the opposite reason—that they could see all that was going on in the ward from any one part of it.

My own feeling—after seeing Antwerp Circular Hospital, Johns Hopkins, and Liverpool—is in favor of the circular ward. After the first strange appearance has worn off, it is not difficult to see that on a limited ground space ventilation can be more efficiently secured, and aspect, of such prime importance in pavilion wards, where those with a northern frontage always appear colder and darker, may in the circular be almost neglected.

The private wards at Johns Hopkins Hospital are so well patronized that last year they produced an income of £8,000 for the hospital.

Nearly all the public hospitals in America have private apartments attached for paying patients, who are taken in at fees ranging from £2 to £10 a week; and private hospitals are much more common than with us, as it is fully recognized that a patient's chance of recovery, especially in surgical cases, is much better in a properly equipped institution than at home.

The pathological and bacteriological laboratories form a part of the building; and though this arrangement was made temporarily, it has been found to work so satisfactorily that it is now agreed that they shall remain permanently.

After going round the hospital with Dr. Hurd, I accompanied Dr. Halsted through the surgical wards. There was a dearth of interesting cases, but what I did see was novel and good.

Dr. Halsted has written on the Treatment of Wounds, with especial reference to the value of Blood-clot in the management of Dead Spaces, and showed me an interesting case bearing on this. A middle-aged man had necrosis of the lower end of the femur, for which he had already undergone three unsuccessful operations in good hospitals during an illness extending over twenty-five years. Dr. Halsted dissected away all sinuses, and thoroughly scraped out a large cavity in the lower end of the femur. Taking the view that this large cavity could not heal, he cut down on the anterior part of the femur, and removed an elongated portion of the middle of the bone, opening up the cavity from the front. He transplanted into the hole a flap of the vastus internus muscle, and this, together with blood-clot, filled the cavity completely. An aseptic dressing completed the proceeding; and at my visit, a few weeks afterward, the leg was healed without a trace of suppuration.

I saw also a novel method for the radical cure of hernia, which was said to be giving excellent results. Dr. Halsted's operation is based on the opinion that the presence of the spermatic cord in the inguinal canal is an important factor in the causation of hernia and the prevention of a radical cure. He consequently makes a new passage for the spermatic cord in the abdominal wall higher up than the internal ring. The incision begins at the anterior superior iliac spine, and ends internal to the inner pillar of the external abdominal ring; dividing skin, external oblique aponeurosis, internal oblique, the part of transversalis muscle exposed, and transversalis fascia, the whole length of the skin incision. The spermatic cord is then separated to the upper level of the internal ring. The sac is isolated and drawn forward with the exposed peritonæum through the wound. The opposed peritoneal surfaces are then brought together along the line of incision by a series of quilted sutures, and the redundant peritonæum and sac clipped away close to the line of sutures. The cord is now brought through between the muscles near the upper end of the wound, and the divided muscles are brought into apposition by a second row of quilted sutures. The aponeurosis of the external oblique may be included in this or separately sutured. Finally, the skin wound is carefully sutured, leaving

the spermatic cord between skin and aponeurosis. No drainage-tube is required.

I next went to Dr. Howard A. Kelly's gynecological clinic, one of the most interesting medical sights in America. Dr. Kelly is a young man—only thirty-five—and has attained his present position solely by his own work and ability, which count, I fancy, more in the New than in the Old country. His results in abdominal operations can scarcely be surpassed, and I was much impressed by the thoroughness of all his work. He has a special theatre and wards of his own, and has described those and his method of working in full in the Johns Hopkins Hospital Reports for 1890. The combination of asepsis and antiseptics described is such as is employed at most of the surgical clinics with a strictness not frequently to be seen in this country, and I have purposely left distinct mention of this important subject till I could do it full justice.

[The author then makes copious extracts from Dr. Kelly's writings, and continues as follows:]

Such are Dr. Kelly's directions, and they give me the impression of carrying out surgical principles, according to our present lights, in a practical manner and one approaching perfection. American surgeons do not forget that all recent advances in wound treatment originated with Sir Joseph Lister, and admit without hesitation that his researches have revolutionized surgery.

They claim that their hospitals and nurses are better than ours, and the first I can not deny. The American nurse, though, is a copy—in costume, manners, everything—of the Nightingale sister, but to my mind there is no nurse so perfect as a good English one.

Before leaving the subject of the Johns Hopkins Hospital it will be well to mention that it has the reputation in America as a training school for nurses, efforts being made by means of lectures to give them a sufficient amount of information. The syllabus of lectures includes elementary anatomy and physiology; hygiene, with special reference to ventilation, heating, and drainage; bacteriology, especially in its application to surgery and medical practice; all the surgery required to insure a certain amount of appreciation of what is being done, and enough of medicine to make the reasons for certain lines of treatment intelligible. A satisfactory examination must be passed on the subjects included in the lectures and on cookery—theoretical and practical—before a certificate of efficiency is given.

Is this too much, or are we doing too little for our nurses? I think the fault is on our side. The nurses are interested in such work for its own sake, and the smattering of knowledge so gained helps them to take a more intelligent interest in surgical methods, and naturally increases their efficiency.

The *City Hospital* at Cincinnati is an old building, but does a great deal of good and useful work. I spent a pleasant and profitable morning with Dr. Conner, surgeon to the hospital, who showed me several simple fractures put up in plaster-of-Paris bandages. Here, as in most American hospitals, it is the rule to put the limb up at once in a plaster bandage over a thick layer of cotton wool. About the end of the first week, all being well, the bandage is taken off, the position of the limb examined, and another bandage firmly applied. This is left on for the remaining five or six weeks of treatment. This practice also obtains in all the German hospitals I have visited, but is adopted only partially in the British Islands. Dr. Conner told me there was now a rage on the radical cure of hernia by different methods, but that he thought possibly ligature of the neck of the sac and its removal were sufficient and as satisfactory in result as more elaborate proceedings.

He also took me to a large Catholic hospital in Cincinnati, with over 200 beds. It is managed by Sisters of Mercy, and there is no resident surgeon. The wards are small—in fact, it is a large ordinary house, the private rooms of which have been converted into small wards. It is remarkably clean and comfortable, and has an air of homeliness about it which is wanting in the ordinary hospital ward. Is this not the model hospital of the future?

In Chicago I saw Dr. Senn, who has recently removed there from Milwaukee. I had no opportunity of seeing him operate, but learned from him in conversation that he had given up the use of dry decaided bone plates, as originally recommended by him, for in one case of

gastro-enterostomy the patient vomited the plates, and in a second case the plates had escaped from the abdominal wound. Both patients recovered, but, in spite of this, he now prefers plates kept in a mixture of equal parts of spirit, glycerin, and water.

*The Massachusetts General Hospital, Boston.*—Owing to the kindness of an old Vienna friend, Dr. Williams, physician to the City Hospital, I spent a most pleasant and profitable morning with the staff, to whom he gave me an introduction. Everything, including hospital, staff, nurses, and all else, is decidedly English at Boston. It seemed none the worse for that.

I first saw Dr. Cabot, surgeon to the hospital, do an ovariectomy. The operation was performed in a special theatre, as all laparotomies are at this hospital, which was quite isolated from the main building, and had special wards in connection with it, much the same as at Johns Hopkins Hospital.

Worsted quilted in gauze bags took part of the share in the sponging, though sponges were used too. The case I saw operated on was a tumor of large size, and several vascular adhesions were torn through, so that some blood necessarily got into the abdomen. The majority of surgeons in this country would have washed out that abdomen and drained it. Dr. Cabot did neither. He, however, sponged it dry and clean before suturing. So far as I could judge, a reaction has commenced in America against drainage and washing in abdominal surgery, as I several times heard both condemned as mischievous.

Dr. Cabot also showed me two hysterectomies for fibroid, clamped outside, convalescent, and a bad case of double pyosalpinx doing well after operation. The results of abdominal surgery in the hospital are excellent, as one can well believe, after seeing the care taken of the patients, and the strict attention to every detail enforced. In this hospital and at the City Hospital the general surgeons do all the operative gynecology, and all over America the general surgeon does a great deal, possibly the greater part, of this work. It is settled on the other side of the Atlantic that abdominal surgery, at all events, is a branch of surgery, not of gynecology.

A case of excision of the ankle of Dr. Cabot's interested me. We would call it erosion or arthrectomy, for the old formal excision is not what was performed. The ankle joint was opened by a semilunar incision on each side, curving round either malleolus and missing all tendons, vessels, and nerves. The astragalus was found diseased, and excised; for, as Dr. Cabot explained to his class, if any disease at all exists in the astragalus the whole bone must be removed, its defective vascular supply making repair difficult. The os calcis was extensively diseased, but the tubercular foci were scraped and gouged out of it with good hopes of success, for its vascular supply is so good as to favor healing. The malleoli were left intact, and it was considered fortunate that this could be allowed, as they form an important buttress and support to the foot. Some loose cartilage was scraped from the ends of the tibia and fibula, and all granulating tissue and infiltrated structure removed. The wound was then filled loosely with iodoform gauze, and dressed in the ordinary way. Excision of joints is somewhat of a specialty at Boston. Dr. Scudder has published some excellent results, but all over America this is a common operation, and leaves an excellent and serviceable foot. Sixteen years ago my brilliant and revered teacher, Dr. Heron Watson, frequently excised the astragalus in such cases; since then I had not seen it done, or heard of it again, till now.

In such a case nine out of ten surgeons in this country would have done Syme's amputation, and I venture to say so in the operating theatre. Imagine my surprise at being told that, if amputation had been necessary, Syme's would not have been the operation selected; that Syme's was perhaps the best operation for a wretchedly poor person; but there were few such, who could not afford a proper artificial limb; and that, where money could be obtained for an artificial substitute, amputation at the lower one third of the leg was the operation of election. This was said by one of the distinguished surgeons of the hospital, and all my remarks, even quotations from Mr. Cathcart, failed to make any impression on his opinion.

Bigelow was a great benefactor to the hospital, and his name appears more than once in going round it. An operating chair in the theatre, devised by him, is a marvel of complicated ingenuity.

Attached to the operating theatre is a room for examining patho-

Original Communications.

A CASE OF SCLERODERMA.

By JOHN DUNN, M. D.,  
RICHMOND, VA.

J. W. H., aged thirty-four, negro, gave the following history: When he was between eleven and twelve years old there appeared on the right ala of his nose a small, hard growth resembling a wart. It began to grow larger and he picked it, and then tried various wart remedies to "carry it away." At times it bled quite profusely when parts of it were scratched off. He then sought a physician, as this growth increased continually. "Blood remedies" of all descriptions were taken internally, until, after years of trial, his physician said "blood remedies were useless." Numberless ointments were used; in spite of these, the affection spread. At times it would disappear partially, only to reappear in the same places. The process remained for years confined to the region about the right ala of the nose, choosing rather to spread to the right than to cross the nose. Finally it attacked the left ala, and thence spread across the left side of the face. When about twenty-two years old the process had extended up the nose as far as the eyelids. Then followed a history of immense swelling of the lids, with discharge from between them. The eyes were very painful. As the lids went down, there remained a sensation as of grit in the eyes. Some sight remained, although, as the irritation was permanent, the sight grew dimmer, and at the end of three or four years he was totally blind. He suffered intensely with his eyes during this period. About four years ago the process had reached his ears. About five years ago it began to "work its way" into the nose and to attack the gums. At no time has the facial affection been painful, nor has there been any itching, except when the diseased surface would break down, and even then the itching was slight. More itching at the corner of the mouth than elsewhere. Occasionally the "eyes" itch. Such is the negro's account of his case, which, though far more accurate than could be given by most of his race, must not be considered as exact, both because of the long years during which it has existed and because the power of exact description in the negro is not over-well developed.

The accompanying cut, from a photograph taken at the time of his coming to the Richmond Eye Clinic in 1891, gives a fair idea of the negro's appearance. The photograph is at fault in many details, which the following description will endeavor to correct: The skin of the face, from about an inch and a half above the eyebrows to two inches below the chin and extending laterally on both sides to the back of the ears, is thickened, infiltrated, and has a hard, elastic feel; in places the infiltration is denser than at others; the skin is immovable over the surface beneath, consequently the expression never changes. The patient is unable to shut his mouth, to such an extent has the infiltration affected the skin of the lips. Most of the surface of the affected area is black and has a shiny look; in parts, however, apparently where there has been at some time more or less irritation with ulceration—perhaps an eczematous condition—the pigment of the skin has to a great measure been destroyed, and the surface here resembles patches of leucoderma, a disease not uncommon in the negro race. The places showing the loss of pigment are two patches extending downward from either corner of the mouth, the probable cause of irritation being the more or less continuous dribbling of saliva from the mouth, and a similar patch below the right nostril, irritation from the nasal

secretion, also the parts of the skin over which the lacrymal secretions flow, just below the "eyes." All of these places are to a certain extent ulcerated, and secrete more or less clear serous matter. The fibers of the orbicularis oris still retain some power, as a slight movement in the lips can be detected when the

FIG. 1.

patient is told to try to shut his mouth. An endeavor to open the mouth wide causes the glands situated along the mucous cutaneous boundary line—and these glands must be greatly developed—to secrete profusely, so that there appear in the upper lip two or three lines of beads of clear mucus, about two mm. apart, the whole length of the upper lip. The same thing occurs in the lower lip, only here there appear three or four irregular lines. These beads of mucus attain the size of a millet seed, and remain, with no inclination to spread over the surface of the lips, for minutes at a time. The lips from time to time crack and bleed, as do the gums of the upper jaw, that part above the eight central teeth. This part of the gums is swollen and hard, and presents the appearance of a disposition to bleed easily. The appearance presented by the gums here is not unlike that seen in a case of hare-lip, where the gums have been exposed for years to the action of the atmosphere and have not received the proper covering and the influence of the mucous moisture, though they are more swollen in this case, and somewhat resemble epulis in its earlier stages. The question arises, then, naturally, whether this condition of the gums has resulted merely from a lack of the protection the upper lip affords, for in the above case the upper lip is so thickened and infiltrated that it is pulled away from this part of the gums and does not furnish them a covering, or are the gums infiltrated by the same process which has attacked the lips? This hypertrophied condition of the gums does not extend beyond the first molar on either side, and is confined to the anterior aspect of the gums. Were this all, it would be fair to suppose that the process had not extended to the gums, but that the swollen condition of the gums was due to exposure and lack of normal moisture. There are found, however, in the region of the rows of glands, just behind the front upper teeth, distinct evidences that some abnormal process has attacked them, for in two or three places

the mucous membrane is drawn together and puckered as if there had been some ulcerative process which, in healing, had drawn the immediately contiguous tissue into itself. The mucous membrane, however, does not here appear to be thickened, nor does this process seem to have extended to the whole of this region. The appearance presented by these drawn spots is very peculiar and unlike anything I have ever seen.

The entrances to the nostrils are very small; it is highly probable that, as the process extends, they will be entirely closed. The entrance to the right nostril is circular and has about the diameter of a lead-pencil; that to the left is also circular, but not more than half the size of that leading into the right nostril. These holes present the appearance of being punched out of the face. Perhaps it would be more correct to say that these holes lead directly into the nose, since the alæ are so infiltrated, thickened, and stiff that all the functions of the nostrils are utterly done away with. The cutaneous and movable cartilaginous part of the septum dividing the nostrils below has been destroyed down to the permanent cartilaginous plate of the true septum, so that the partition between the two nostrils, as seen from below, is not more than the diameter of a lead-pencil in length, and is formed by a part of the cartilage of the true septum. There is, however, no ulceration here. The skin at the angles and sides of the nostrils is so infiltrated as to obliterate all folds at the side of the nostrils and make the whole on a gradual slope with the cheek bones. (This is not well shown in the photograph.) As far as examination of the nose anteriorly can be made, the intranasal cavities appear to be free, and to show no hypertrophies.

The "eyes" present the most remarkable part of the picture. There remains not a vestige of a lower lid on either side, skin and mucous membrane alike having been entirely destroyed. On the right side there remains a part of the upper lid with about half a dozen coarse lashes in a clump near the external angle. The eyeball has disappeared, and where there should be an eye, is only an oblong, fiery-red raw surface. This red surface, except at the outer corner, where it makes a slight furrow, is almost level with the cheek, so that one says: "Were that ulcer to be covered with skin, no one could say there had been an eye here." On the left side the same condition obtains, except that the upper lid remains and the raw surface is much deeper, and there is clearly some mucous membrane which is bound down to the central part of the raw surface. This raw surface, as on the right side, is deepest at the external corner. There remains some little power of motion in the levators, and on the left side it can be plainly seen that the straight muscles of the orbit have not been destroyed, as the patient can at will contract the mucous membrane puckered at the central part of the raw surface. The secretion from these raw surfaces is, for the most part, clear tears, which run in some profusion over the cheeks. This secretion comes chiefly from the external corner, where a probe will show that in either "eye" there exists a fistula leading to the lacrymal gland, which must have remained, in great measure at least, uninjured. At the internal angles of these raw surfaces all evidences of the once existence of lacrymal puncta and canaliculi have been destroyed. The skin in the region of the eyebrows is infiltrated, and the greater portion of the eyebrows has disappeared. The process has extended across the face to the ears, which are only in part infiltrated. The parts thus far attacked are the lobules, which are much thickened, and the outer edges of the lobes. The process has reached the tragus and antitragus, though it has not attacked the canal. The ears show evidences of superficial ulceration of the infiltrated parts, probably due to the pressure to which these parts are subjected when the patient is lying down. There can be but little tendency for the affected parts to break down of themselves, as these

superficial ulcerations heal with rapidity. The skin of the face, as said above, is infiltrated and hard, and in most places has a shiny look, and to the touch resembles rubber. It is not, however, everywhere infiltrated to an equal degree, as there are areas where the infiltration is thicker and denser than at others. About the center of either cheek are several more or less contiguous areas where the skin is so densely infiltrated as to be knotty. These areas are slightly elevated above the adjacent skin, and the total space occupied by them on either side is about a quarter of an inch by an inch and a half. These areas are distinctly nodular. Beneath the angle of the jaw on the right side are two hardened areas which are, most probably, enlarged lymphatics. On the forehead the skin is as yet but slightly attacked, and while the process is the same as that below, the skin has not been infiltrated to the same degree. At almost all points the line of demarkation between the healthy and the infiltrated skin is accurately defined. The affected parts are not painful or sensitive on pressure. During the few weeks the negro remained in Richmond a wash of warm bichloride (1 to 2,000) was kept, for varying intervals during the day, applied to his face. The only noticeable change following this was that the infiltrated skin, especially over the forehead, lost much of its leathery feeling and shiny appearance, and became more or less wrinkled and movable, as though these parts were undergoing an involution to their normal condition. This, however, the negro said it would do from time to time without any treatment, but afterward it would get dense again and spread further. This being the case, it is impossible to say whether the bichloride solution had any real effect upon the process. The change following the use of the solution was, however, a marked one. The teeth are well preserved. The skin covering the other parts of the negro is healthy. Nor does the negro's general health seem to be impaired by this condition. Appetite is good. At one time he was liable to colds in the head, but rarely suffers from them now. Is a married man and has several healthy children, one of whom, a girl about twelve years of age, leads him about from place to place. Examination of the throat shows the tonsils to be greatly hypertrophied, with marked evidences of adenoids of the nasopharynx. The application of the palate retractor shows the posterior nasal picture to be normal, showing that the process had, at least, not extended through the nose so far as to attack the posterior parts of the turbinates or septum, while examination of the nose anteriorly, as said before, makes it doubtful whether the process has at all extended into the nose proper. One of the tonsils was removed pretty thoroughly with a snare. A severe inflammation of the pharynx, pillars, and soft palate of the side from which the tonsil had been removed followed, and with it immense œdema of the uvula. For a few days serious consequences were feared; under treatment, however, the inflammation subsided and the wound healed perfectly. The cause of the inflammation is, probably, to be sought in the negro's being unable to properly expel the accumulated secretions from his mouth, owing to the stiffened condition of the lips and cheeks.

*Remarks.*—While the case has many characteristics which make it, in all probability, a case of scleroderma, there are certain features pertaining to it and to its history which at least suggest a rhinoscleroma. The negro states that a "hard, warty" growth appeared about twenty-two years ago at the external edge of the right nostril; that it remained years in this region, showing little or no tendency to spread beyond it; that in his endeavors to remove it he made it bleed; that this growth then, finally, began to extend up the side of the right nostril and then crossed over and attacked the left nostril. Owing to the length of time

that has elapsed since then it is impossible to determine the nature of this hard localized growth. The nose now shows no evidence of a circumscribed nodular growth, but its skin is equally infiltrated, so that one may not say that one part is more infiltrated than another. It can not now be said whether this originally circumscribed, nodular growth had a tendency *per se* to bleed, or whether this tendency to bleed was developed under the various attempts to cause it to disappear by "wart remedies." The growth, however, was not syphilis, as proved by the treatment to which the negro has been subjected, nor was it epithelioma. Nor does the present condition of the skin at all suggest cicatricial keloid, a condition common enough in the negro race. Whatever the original growth was, it has left no trace of itself behind; but whatever it was, it proved to be the starting point of a sclerodermatic process, which has involved nearly the whole face. The tendency to, at times, partially resolve is characteristic of scleroderma; but I can find no record of a case where this seeming repeated tendency to involution to recovery proves to be followed by an extension of the process even beyond the limits from which the beginning involution began. The fact that it is symmetrical points to scleroderma. What the hardened, circumscribed areas in the cheek mean it is difficult to say. It is possible that at some time there may have been ulcerations in the places now occupied by these nodular areas, the process of healing giving rise to a cicatricial keloid condition; on the other hand, their general appearance is not at all suggestive of keloid as seen in the negro. I cut into one of these areas to see if there was any broken-down tissue beneath. It was firm, elastic under the knife, cutting like scar tissue. Again, if these infiltrated areas represent scar tissue, some process different from simple dermatitis must have existed at these places to have given origin to them, since at the other places—*e. g.*, beneath the corners of the mouth, where there has existed superficial inflammation—no such result has appeared. The process seems to have been unwilling to attack the mucous surfaces, unless the swollen condition of the gums show that it has invaded them. I think it more probable, however, that, as above stated, this condition of the gums has resulted from their exposure. What the small, contracted areas in the mucous membrane behind the upper front teeth mean I do not know. The tissue surrounding them is, however, not infiltrated. A more interesting problem is furnished us in the condition of the eyes. By what process did the lower lids disappear? We have here not to do with a severe case of ectropion, or entropion, or partial destruction of the lower lids, such as might result from an inflammation or a circumscribed abscess, but with a destruction so complete that, from external to internal canthus, not a vestige of them remains. Skin, muscle, and mucous membrane have entirely disappeared. It is as though some one had seized the free edges of the lower lids and pulled them from the cheek as far as possible, and then shaved the lids off close to the cheek. There remains not one shred of scar tissue to show that they disappeared piecemeal. About twelve years ago, says the negro, the process, which had up to that time confined itself to the region of the lower nose and adjacent cheek, spread upward and reached the lids,

following which came an intense inflammation of the eyes, which remained closed by the swelling for some time. Much secretion from between the lids. Then followed diminution of the swelling of the lids, with great pain in the balls, which pain remained until the sight had been entirely destroyed. To one who has seen much of eye troubles among the negro race this bit of history means nothing, or very little, and even less when twelve years have elapsed. Having seen the case only after the destruction of the lower lids had become complete, the manner of their disappearance must remain a conjecture. It may not, however, be uninteresting to look into the cause which might have led to such a condition. The present state of the upper lids, except for the infiltrated condition of the cutaneous surface, is such as might be the result of most any of the severe inflammations of the conjunctiva if continued for a length of time. The history, as given by the negro, suggests purulent ophthalmia, with corneal ulcers, perforation of the ball,

FIG. 2.

following which its gradual destruction. There are no remains of the eyeball in either socket, unless there be a part of the sclerotic, which may be left, as in the left "eye." There are some movements at the center of the inflamed surface, where the eye was, which suggest that the muscles have their insertion there. How did the lower lids disappear? Could the destruction have been begun by an abscess occurring at the time of the ophthalmia, and have been completed in the course of years by the continuous pouring over them of the muco-purulent, and lacrymal secretions? This seems little probable since these same tears and other discharges have not been able to destroy or to do more than produce a slight form of dermatitis of the skin below the orbit, and they have continued ever since the lower lids were destroyed. The eyes were three or four years in "going out," during which period the negro suffered intensely. This is the history of perforations and their results.

In seeking the possible causes of the destruction of the lower lids, the following case from among a collection of

photographs of the rarer affections that came to the Richmond Eye Infirmary presented itself, and a short history of the case may not be out of place here: James A., negro, aged twenty-three, had suffered every spring for several years with some eye trouble the nature of which he could give no better description of than that "the light hurt his eyes"—words used by the average negro to describe any eye affection whatever. (Probably phlyctenular inflammation was the trouble.) In June, 1891, his eyes became much inflamed, and *in a week* both eyes had assumed the appearance shown in Fig. 2, except that the right eye presented a condition exactly similar to that of the left eye in the cut, the less swollen appearance of the right lower lid being due to the fact that a part of the tumor of this lid had been removed by a physician before the negro appeared at the clinic, which he did the latter part of July, 1891. The condition of the eyes then—that is, seven weeks after the trouble began—was as follows: Patient was entirely unable to open either eye; the lower lid of the left eye was a huge smooth, ovoid mass, covered with shining mucous membrane; the cutaneous surface of the lower lid was bent over by the weight of this tumor until it lay in apposition with the skin of the cheek; all endeavors to open the eye resulted in a slight constriction at the base of the tumor, caused by contraction of the orbicularis fibers; this swelling of the lower lid was seemingly a true hypertrophy of the tissues beneath the mucous epithelium, most likely of the adenoid reticulum of the mucous membrane; the secretion from the eye was small in amount in comparison with what might have been expected, and was rather sero-mucous than purulent. The upper lid was apparently elongated, and responded, but in the slightest manner, to the efforts of the levator; and, though its mucous membrane was in an inflamed condition, especially in the *cul-de-sac*, there was no such swelling anywhere as the lower lids showed. The lids of the right eye were in a similar condition, except that, as stated above, a piece had been removed from the mass in the lower lid. Both corneæ were almost completely surrounded with superficial ulcerations, or leucomatous patches, showing that ulcers had once existed. While no perforation of the cornea could be made out, there had been a severe double iritis, with adhesions to the lens. As said above, there was complete eversion of the lower lids, which infiltration or hypertrophy had transformed into helpless masses. When the negro was told to shut his eyes there appeared a constriction at the base of these tumors, due to contraction of the outer fibers of the orbicularis. This condition of the lower lids I have seen in one other case, also in a negro, the trouble being undoubtedly purulent ophthalmia, as was also the case in the subject of the accompanying cut, although the stage of active purulent discharge had passed when he came to the clinic; and it is not improbable that a similar trouble was the cause of the complete destruction of the lids in the case of the negro with scleroderma. The history would, then, be about as follows: Purulent ophthalmia; great infiltration and complete eversion of the lower lids; great stretching of the skin at the place where the cheek and lower lid meet; perhaps stasis of blood-current in the skin here, with ul-

ceration and destruction of the skin along the line of tension. Thus, could the entire lower lid be separated from its attachments, while the condition of the lids would be most unfavorable to any reunion of the parts, afterward slow, continuous ulceration could destroy the lids entirely, especially when already a pathological process existed in their cutaneous covering. The case of James A. has been added here not because it answers entirely to my satisfaction the question of how the lids in this case of scleroderma disappeared, but because it offers a more probable solution than any other that suggests itself.

#### THE RELATION OF DISTURBANCES OF THE MUCOUS MEMBRANE OF THE UPPER AIR PASSAGES TO CONSTITUTIONAL CONDITIONS.\*

By BEVERLEY ROBINSON, M.D.

To establish the connection between constitutional conditions and disturbances of the mucous membrane of the upper air passages is at times a relatively easy matter. In more frequent cases it is difficult to make out clearly the interdependence of the general and local conditions. In a certain proportion of instances, even after the most careful repeated examinations, one can not but remain in great doubt as to whether there be any common causation of the diathetic state and the physical changes observed in the upper portion of the respiratory tract. In order to form just ideas on this subject it is important to investigate without prejudice and to scan every clinical case observed in the most thorough and searching manner. It is also required to attach due weight to the observations of learned men who have preceded us in their practice of the healing art. While this is true, we should not be over-tolerant of opinions held in the past, if later advances in our science and art prove that former beliefs are erroneous, or that clinical data handed down are unreliable by reason of lack of precision in the methods employed.

Still, there are certain judgments which have been tested so frequently and so long that we should be very careful lest we abandon them without sufficient reasons.

These remarks are but a prelude to the statement that the old notion, which was widespread, of a constitutional condition influencing every local state is fast losing ground with the modern practitioner. To my mind, there is little doubt that very many physicians of the present day are inclined to localize most human ailments to the exclusion practically of the diathetic influence. This tendency naturally makes local treatment of primary importance whenever any real disease is present which requires remedial interference. In no special departments of medicine or surgery is my statement truer than it is in those of laryngology and rhinology. Just why this view of our art has arisen may be clearly explained, as it seems to me, by the consideration of a few facts. First, modern thought in laryngology and rhinology, as in every special branch, has forcibly, as it

\* Read before the American Laryngological Association at its thirteenth annual congress.

were, limited the mental horizon of the observer. Such an one can not delve into general medicine. It has become too large and also too changeable. New discoveries and new ways of doing things are being added each day to every department. The busy and successful man—the one upon whose judgment we most rely—can not find time to go outside his special field of work and see and hear things as some others see and hear them. The result is that he is not wholly convinced of the truth of things spoken and written by those about him, as they do not thus come before his mental vision. Besides, whenever the throat specialist finds that in some instances which have come under his care a particular line of treatment has been beneficial, he is apt to assume that he can lay down general laws which should govern the action of others, and he does not allow enough latitude to the various aspects according to which even the simplest case can be regarded. These reflections do not prevent me from fully recognizing the great strides in advance that have been made latterly by the specialists in laryngology. No one is more willing to admit that mechanical ingenuity and operative interference have relieved or cured many patients in whom the outlook without their aid was well-nigh hopeless.

And yet the human body is formed of many different organs whose structures and functions are linked indissolubly to one another, and we can not ignore any one of them as being wholly unimportant in its influence upon the others. So it is that we start out with the thought that the relation of disturbances of the mucous membrane of the upper air passages to constitutional conditions are various and intricate.

Sometimes the mucous membrane itself, by reason of its diseased condition, which has arisen in some accidental or wholly obscure manner, seems to be a focus for diseased germs—the habitat in which they will flourish and propagate readily—finally to end in constitutional disorder of an acute or chronic type. Frequently the diseased constitutional condition precedes, indeed, all physical or rational evidences of local disturbance in the mucous membrane of the upper air passages, and it is only after weeks and months that the general disease is plainly manifest in the alterations of function and structure which are clearly discernible.

The constitutional condition may be one of those in which heredity or contagion plays an essential part as an efficient causative factor, or one in which the habits, mode of life, and surroundings are obviously the powerful agencies at work, or, finally, one in which the mere development of the individual seems to be the seed which will cause the local disturbance to come into being and grow at a certain period of life with more or less certainty. The constitutional conditions we are called upon to consider may be acute or chronic. In the former we find the fevers, and among these the fevers which come to mind most prominently are typhoid fever, the eruptive fevers, and those due to malarial poison. Then we have diseases of a general and acute character, like diphtheria and acute miliary tuberculosis, which unquestionably produce different disturbances of the upper air tract. As I understand the subject

of discussion, however, it was not intended to include in it the affections just mentioned, with, perhaps, the exception of the relation existing between malarial diseases and disturbances of the upper air passages. Doubtless the section had in view chronic tuberculosis, syphilis, scrofula, carcinoma, gout, rheumatism, lithæmia, alcoholism, etc. This list, just as the former one, can be largely added to, but in so doing I should be going beyond the short introductory message that is properly expected from me. No one present, I am sure, can doubt for a moment that the constitutional condition which is shown in general chronic tuberculosis finds for itself a very frequent localization in the upper air passages. Particularly as laryngologists are we called upon to recognize this sad fact in our diagnosis and treatment of intralaryngeal disease.

Whenever laryngeal tuberculosis is distinctly evident, the clear-cut relation between the constitutional condition and the local disturbance is recognized at a glance. By this statement I do not mean to say that it can be known at once how and when the tubercular deposit has taken place in the larynx. I simply wish to affirm that there can be no doubt as to the precise nature of the disease. It can not be confounded with the ordinary chronic catarrhal laryngitis, which exists as a primary affection, or as a sequela of a mild form of acute laryngitis. The ulcerations in the larynx, the history of the patients, and the intrapulmonary condition are all sufficient, as a rule, especially when the disease is at all advanced, to allow us to make the differential diagnosis with perfect ease. If, however, the laryngeal inflammation is relatively slight in an anæmic patient in whom the chest signs are negative and no abrasion of tissue exists locally, it becomes a very delicate matter positively to decide what the exact relation is between the disturbance of the laryngeal mucous membrane and the constitutional condition. The general cachexia and impaired nervous nutrition influence very much the nature and course of the catarrhal inflammation of the larynx, and for a considerable time we are left in doubt as to whether these conditions will be followed or not by the local deposit of tubercle in the vocal organ. It is probable that, whenever the ulcerative or hypertrophied typical condition of the laryngeal structure is reached, it is brought about, in part at least, by the constant irritation which is occasioned by the passage of discharges over the laryngeal mucous membrane and by the efforts made by the patient to get rid of them by expectoration. The additional movements thus occasioned in the larynx unquestionably favor the local deposit of tubercle and the development of more marked laryngeal complications.

As in tubercular disease, so in syphilis, a chronic catarrhal laryngitis is often greatly modified as to its course, its symptoms, and its appearance by the underlying constitutional condition. A syphilitic laryngitis presents, even without ulceration, a deeper, more persistent coloration than that due to simple catarrhal inflammation. Moreover, the painful symptoms accused by the patient are not at all in proportion with the apparent degree of the inflammatory condition. Again, the use of specific treatment with mercury and the iodides benefits the patient so rapidly and

manifestly as to leave no doubt in the mind of the physician as to the distinct causal relation of the syphilitic disease to the disturbance of the laryngeal mucous membrane. In many cases the acknowledgment of the patient in regard to previous syphilitic infection will enable us to reach a decision in some very obscure cases. Of course, if the intralaryngeal congestive condition advances to ulceration, this of itself is sufficient to distinguish it from chronic simple catarrhal laryngitis. The irregular outline, yellowish exudation, and red areola of the syphilitic ulcer are readily distinguished from the ashy-gray hue and raised, thickened, pale borders of phthisical ulcers. Its march is more rapid and its symptoms are less painful. In secondary syphilis especially hyperæmia often attacks the nasal mucous membrane, and in these cases occasions the symptoms of ordinary nasal catarrh. The tendency to the formation of ulcers or mucous patches on the erythematous surface is quite marked, and particularly so among the poor, or with patients who are smokers or take snuff. The syphilitic erythema is sometimes in patches or punctate. It is difficult to differentiate from ordinary catarrhal inflammation of the pituitary membrane, except by the fact that the hue is more dusky and there is less apparent irritation than there would be from a hyperæmia dependent upon a cold. Mucous patches are occasionally seen in the larynx and trachea, but they rarely become extensive in these situations, and disappear after a few weeks of mild treatment. The diffuse connective-tissue hyperplasia, without ulceration, which occurs in the larynx in the tertiary stages of syphilis is accompanied by a dark-colored mucous membrane and a general thickening which affects the soft tissues of this organ.

Among the disturbances of mucous membrane of the upper air passages which are obviously connected with scrofula, an inflammation of a low type is the one most frequently encountered. In this form the exudation is markedly thick and sticky, and the tendency to the formation of dry scabs is most pronounced. Concomitantly we have different eruptions on the skin which manifest the diathetic nature of the lesions. Impetigo of the scalp, face, and eyelids, eczematous eruptions around the ears, in the auditory canals, and upon the upper lip and at the nares, are commonly met with. The bones, periosteum, and synovial membranes may also show evidences of scrofulous development which, taken with the affection of the mucous membrane, leave no doubt as to the nature of the underlying dyscrasia. The more destructive ulcerative lesions of scrofula as affecting the pharynx and larynx are rarely seen in this country as compared with many parts of Europe, and notably with Germany. Unfortunately, we do occasionally meet with them in the throat in the form of those ravaging lupoid conditions which occasion such deformity and interference with normal function. The patients thus affected are often the offspring of intemperate, syphilitic, or phthisical parents. The hereditary influence is, however, not always well marked, and the scrofulous diathesis appears to be acquired by reason of poor food, lack of sunlight, and unhygienic surroundings. The alternation in these cases between a coryza, catarrhal conjunctivitis, otorrhœa, and ulceration of the cornea is fre-

quently one of the most evident marks of the constitutional relation to the disturbance of the mucous membrane of the upper air tract. The inflammations of the larynx and bronchi are frequent and obstinate. Not seldom they extend to the pulmonary alveoli, and tuberculous deposits in the lymphatic ganglia and lung structure are prone to take place sooner or later. The diagnosis of the scrofulous disturbance of the mucous membrane of the upper air tract usually is determined in great part by its low grade of reaction, by its singular obstinacy or duration, and by the peculiar, characteristic changes which appear concomitantly and give evidence of the presence of the constitutional condition. One statement must be graven in the mind of the observer, because in regard to this subject there arise great and lamentable errors—viz.: that those chronically seamed and scarred throats, with distorted pharynx, the result of former destructive ulceration, which are not infrequently met with both in youthful and adult subjects, are not of scrofulous origin, but unquestionably syphilitic in the very large majority of cases. Koch's late discovery of tuberculin appeared at first to be of very great value in making, through injections of it, the differential diagnosis particularly in instances in which a syphilitic history or parentage could not be traced. Unfortunately, it has failed to accomplish this end in just such cases, and we are again obliged to fall back upon the results obtained, when cases are seen soon enough, by pushing the treatment by means of an iodide rapidly increased to large, repeated doses.

Of course, when great ravages are already made we can only hope to prevent further destruction and remedy, it may be, alterations in the voice and difficult deglutition by operative interference. Gout and scrofula often exercise a decided influence on the course and manifestations of syphilis as it appears in disturbances of the mucous membrane of the upper air passages. Whenever gout is present the hyperæmia of the mucous membrane of the upper air tract presents a drier, more glazed appearance than when the syphilis is uncomplicated. When ulcerations form in the nasal passages or in the pharynx they are cured more slowly and show a tendency to return which is quite disheartening at times. Finally, the gouty diathesis tends unquestionably to cause nervous symptoms in syphilis, as shown by pains in the throat upon swallowing or in using the voice, which are not always sufficiently accounted for by the evident lesion which is present. Whenever scrofula complicates syphilis the cicatrices of ulcer in the throat take on a more irregular, puckered, and ridged appearance, and are less smooth, thin, and glistening than those distinctly characteristic of syphilis. No doubt, therefore, in many instances the syphilis is really complicated with scrofula, and the resultant ulcerations have about them all the appearances of struma, not unlike what often occurs in entaneous ulcerations. The type of the syphilis is apt to be more inveterate and often attended by destructive bony lesions. The relation between chronic malarial infection and disturbances of the mucous membrane of the upper air tract has been noted by competent observers for a long period of time. In a paper read before this association in June, 1890, in Boston, I made known my experience in

this connection. Frequently a malarial attack is ushered in, not by chills and fever, but rather by repeated sneezing or an obstinate, paroxysmal cough. Upon inspection with the laryngeal mirror or with the nasal speculum, we may only find the usual catarrhal appearances indicative of an acute laryngitis or rhinitis. When we come to inquire into the history of these patients we shall find that these attacks come on periodically, are followed by fever and chills at times, resist ordinary remedies for cold, and are brought into subjection after a short treatment with quinine or Warburg's tincture. Frequently the spleen is enlarged, and occasionally pigmentary deposits or different forms of the *Hæmatozoon malarie* are found in the blood upon careful microscopic examination. In view of these facts, I believe that we can scarcely doubt the relation which exists between the blood dyscrasia and local attacks of the disease on mucous membrane of the upper air tract. Many cases of spasmodic asthma, apparently of the nature of a bronchitic asthma under the immediate dependence of an inflammatory condition of the bronchial tubes, have been signally relieved by anti-malarial agents used remedially, when cauterization of the nasal membrane and sawing the septum had obviously been of little or no benefit. In any case to-day of obscure disturbance of the mucous membrane of the nose, throat, larynx, or bronchi, with a history of possible malarial exposure, and after eliminating other complicating conditions, it is wise to think of blood poisoning from *Hæmatozoon malarie* as being the efficient cause of the morbid symptoms. Judicious treatment, after proper physical and blood examinations have been made, will frequently confirm an uncertain diagnosis in just such cases. It is also true that quinine and Warburg's extract will occasionally fail to be curative in these attacks after a time, and we shall be of greater service to these patients by prescribing for them phosphorus and strychnine in moderate, long-continued doses.

The relation of carcinoma to one of the disturbances of the mucous membrane of the upper air passages has been shown in a detailed and graphic manner before this association last year. It would seem as if in the earlier stages at least of malignant disease of the larynx, some value should be attached to the infiltration of the soft tissues which interferes notably with the movements of the vocal cord on one side, to the existence of a ring of reddened infiltrated tissue around the new growth, and to the cloudy area in the vicinity of the growth which can be demonstrated by the use of transillumination. Of course the lancinating pains, swelling and induration of the glands near the cornua of the hyoid bone, the character of the secretion, and well-defined deformity will be of much value, whenever they are present, in fixing a diagnosis. The appearances of the growth and the general history of the case are often helpful. The absence or presence of syphilis or tuberclosis and the effects at times of more or less prolonged antisiphilitic treatment aid our judgment frequently as to the nature of the case with which we have to do. In like manner the microscopical examination of a portion of the tumor removed before or after death is occasionally of the highest diagnostic importance.

No doubt one of the determining factors in producing malignant disease in the larynx is the frequent occurrence of inflammatory conditions in this organ. The constant use of the voice seems to become a source of local irritation in many instances, and thus the professions of singer, teacher, public speaker, all appear to promote the local deposit of cancerous tissue. The constant inhalation of irritating vapors and dust is also a predisposing cause in occasioning a local hyperæmia which so frequently precedes or accompanies the presence of malignant growths. Apart from all local changes, however, there is always apparently in operation the underlying constitutional dyscrasia which gives the specific character to the morbid lesions. We all know that when the chylipoietic system is out of order or performing its functions imperfectly, repeated and often obstinate pharyngeal and laryngeal irritations are apt to occur. It is only by due attention to this knowledge and by proper direction of treatment in view of it, that we are able to effect cures in cases otherwise intractable.

Chronic alcoholism is often made evident by the congested, excessively irritable pharynx or larynx, and a diagnosis otherwise obscure is thus sometimes readily made. An annoying naso-pharyngeal catarrh, with marked enlargement of the tonsils, is occasionally very distinct proof of the process of second dentition in the young lad or girl. A disordered emotional temperament or a well-marked neurasthenic state is not seldom the underlying cause of recurrent attacks of coryza which have defeated our best-directed efforts at successful local treatment. Luxurious habits and surroundings, sedentary occupations with accompanying chronic dyspepsia and constipated bowels, will sometimes produce irritability of the reflex centers of nose and throat which can only be cured by the exposures of an outdoor life and their accompanying hardships. While this is true, it is also a fact that once the catarrhal inflammation of the upper air passages has taken place, it frequently aggravates very much the pre-existing dyspepsia and the adjoined lithæmic state. Indeed, it is no uncommon thing to hear a patient say that it is the violent hawking and constant spitting from which he suffers every morning on rising that unsettles his stomach at that time, and may continue to cause inappetence or disgust for food during several hours of the day. It is an observed fact, not very infrequent, that patients who have never previously suffered in the smallest degree from any evidence whatever of one of the recognized forms of dyspepsia have developed this condition in a distinct form subsequent to the appearance of a catarrhal inflammation of the nose, naso-pharynx, or the pharynx and larynx. It is probable in such cases that some of the secreted mucus from these organs works its way down the back of the throat and is swallowed, thus starting gastric disturbance. It is also clear that the current of inspired air, or rather the air which is swallowed after passing over masses of mucus or muco-pus, more or less in a state of putrefaction, must be very injurious to the healthy functions of the stomach, or stomach and bowels. It is well known that the "condition of suboxidation and overcharging of the blood and excretions with excretory matter in a state of faulty elaboration" is but too prone to occasion disturb-

ances of the mucous membrane of the upper air passages. The patchy congestion of the pharynx, the epiglottis, ary-epiglottic folds, and ventricular bands is often indicative of this condition. The throat is extremely irritable and the patient suffers from a harsh, dry cough. There is often marked dysphagia referred to the sides of the larynx. Appropriate general medication and hygiene generally bring these attacks to a close in a short time, and thus the therapeutics of the case seems to establish the correctness of the relation between the constitutional condition and the local manifestations.

#### THE SYMPTOMS AND PATHOLOGICAL CHANGES IN THE UPPER AIR PASSAGES IN INFLUENZA.\*

By J. SOLIS-COHEN, M. D.

In presenting a summary of the symptoms and pathological changes in the upper air passages in influenza, let me at once refer to the remarkable paper presented to us in 1889 by our present president, in which he seemed to have recognized a precursor of the recent pandemic in a series of cases which had come under his observation for the previous three or four years. If we carefully peruse this paper and compare it with half a hundred or more of the reports of ordinary and exceptional lesions which have been noted during the pandemic of 1889-'90 in the most diverse portions of the globe, we can not fail to be impressed with the accuracy displayed in Dr. Glasgow's observations. A few such confirmative records will be referred to in foot notes when these remarks are printed.

To confine the subject to the limits assigned for the present discussion, we find from various sources records of a mucoid or, as I would call it, a lymphoid œdema of the palate and pharynx, of the intranasal structures, of the epiglottis, and of the larynx, top and interior. We find records of patches of exudation on the tonsils and on other portions of the throat, much resembling the patches of diphtheria; we find records of œdema of the glottis and death therefrom, analogous to Dr. Glasgow's cases of œdema of the vocal bands, and of sudden death from spasm of the glottis or from sudden laryngeal stenosis.†

We find records of purpura spots on the mucous membrane of the structures already named, and even in the trachea, with recurrent hæmorrhage therefrom;‡ and we find records of mycosis of the tonsils.

There are a few additional manifestations in our immediate domain which have doubtless been observed by Dr. Glasgow during the late prevalence of influenza. These are, as extensions from the nasal passages, inflammation and suppuration in the frontal and maxillary sinuses, in the ethmoidal cells, cerebral abscess, inflammation of the Eustachian tube leading to otitis media, and other lesions of the auditory apparatus; as extensions of the laryngitis,

hæmorrhage\* and abscess;† and as sequelæ, paralysis of the palate‡ and paralysis of the larynx.§

I should likewise call attention to a paper by another fellow of our association, Dr. Seiler, read in the same year before the Laryngological Section of the American Medical Association, in which he presents a summary of some five hundred personal observations of cases similar in character to those described by Dr. Glasgow and with which he had been familiar for about the same period.

Although the ætiology of influenza is not included in the subject of the present discussion, it may be permitted here to remark that the various local but extensively separated telluric disturbances of several kinds that have taken place in the United States within the period comprised in the clinical observations of Dr. Glasgow and Dr. Seiler, and of a few others of like character, link their cases to those which have recently occurred pandemically throughout the globe, and which have not altogether ceased to appear endemically, and that they thus justify the surmise of Dr. Glasgow that the epidemic described by him was to be regarded as *influenza*—a surmise, under the circumstances, of most discriminative acumen.

The symptoms of influenza as manifested in the upper respiratory tract are not at all characteristic, and are recognizable as due to that disease only from their endemic character and the peculiar prostration of the nervous system which attends them, and which in its turn is characterized by suddenness of onset and by great debility of the circulatory system.

These symptoms comprise sternutation, coryza, parosmia, nasal dyspnoea, epistaxis, sore throat, dysphagia, impaired articulation, cough, expectoration sometimes hæmorrhagic, dysphonia, aphonia, laryngeal dyspnoea, spasm of the larynx.

The lesions, mainly catarrhal, giving rise to more or less of these symptoms are not universal. They exist probably in about one fourth of the cases, the remainder presenting the nervous, pulmonary, and gastro-intestinal disorders without catarrhal complication.

The pathological lesions observed in the upper respiratory apparatus comprise catarrhal, hæmorrhagic, and purulent rhinitis; inflammation and suppuration of the ethmoidal, frontal, and maxillary sinuses; acute phlegmonous and œdematoid sore throat; simple acute pharyngitis and œdematoid pharyngitis, general amygdalitis, and lacunal amygdalitis; inflammation and tumefaction of the lymphoid nodules at the vault of the pharynx and in the base of the tongue; pseudo-membranous exudation of the tonsils, palate, pharynx, tongue, and larynx; superficial, œdematous, hæmorrhagic, fibrinous, subglottic, purulent, and ulcerative laryngitis; abscess of the larynx; simple and hæmorrhagic tracheitis—all this but an exemplification of the general Protean characters of influenza in general.

To these must be added submaxillary and cervical infiltration of the connective tissue with lymph, simulating the

more serious lesion known as Louis's or Ludwig's angina, and sometimes compressing the larynx. On incision into this tumid mass there is no evacuation of pus either immediately or a day or two after, but only blood and serum or a sero-lymph exude, as occurred in a few cases I have seen in consultation during the pandemic.

These lesions occur but in a small proportion of the catarrhal cases.

It is to be hoped that some member of the profession with sufficient leisure will study the records of these manifestations with a view of learning their proportionate frequency.

The congestion of the mucous membrane is passive rather than active, due to venous stasis rather than arterial congestion. The color is a violet-red rather than a carmine. The membrane looks sodden, tumid, and pasty from lymph stasis, and from exudations of lymph on the surface. Echy-moses take place in irregular numbers and distribution, and hæmorrhages, for the most part slight, in a certain proportion. In the œdematoid cases muco-lymph, rather than sero-mucus, is discharged from incised wounds, and the release of serum, as in ordinary œdema from venous stasis, is seen but exceptionally.

At a later date fibrinous accumulations are noted at various points upon the mucous membrane. In some cases there is profuse glandular secretion, and in some laryngeal cases the secretion may be seen exuding from the ducts of the glands.\*

The morbid process may proceed to suppuration and ulceration, while in some cases abscesses are formed. These manifestations do not subside with the actual attack of influenza, but often continue for a number of weeks after cessation of all characteristic constitutional symptoms.

In some cases of laryngeal complication, paresis of the laryngeal muscles takes place, chiefly in the domain of the constrictors, and occasionally in the form of paralysis of the recurrent.†

Paralysis of the palate and other paralyzes sometimes occur in the domain of the upper respiratory organs which bear considerable resemblance to the paralysis occurring in diphtheria.

I have seen a number of examples of the tumid, puffy, pasty condition of the mucous membrane of more or less of the mouth, palate, and pharynx, so well described by Glasgow, much resembling ordinary œdema on first inspection, but not fluctuating or pitting under pressure. The tumefaction is often so great as to impair articulation, respiration, and glutition. The rhinopharynx, the interior of the nose, the epiglottis, the borders and the interior of the larynx, may be similarly affected. At the same time, in some instances, there is an analogous tumefaction of the subcutaneous tissues under the lower jaw and in front of the neck, similar in appearance to that of diffuse cellular infiltration, widely known as Louis's or as Ludwig's angina, and giving rise to dyspnoea by compression.

Incision into the tumid portions of mucous membrane

show that the infiltration is not serous but seems lymphous, and the viscid liquid will exude in long strands. During paroxysms of gagging after incision I have seen thick strands reach from the mouth of the seated patient to the spittoon on the floor in unbroken streams. In other cases there is nothing but venous hæmorrhage from the incision, but considerable mucoid or lymphoid material will be expectorated later.

Before the œdematoid condition is reached, the lymph will have made its appearance on the surface of the mucous membranes, whence it is expectorated in thinner viscid strands. The known connection of the lymphoid spaces of the nasal mucous membrane with the subarachnoid and subdural spaces affords a clew for accounting for some of the terrible meningeal and cerebral complications, if we admit that the disease is one affecting the lymphatic circulation as well as the sanguinous circulation. It is probable that both are impaired by parietic conditions of the vasomotor system as a direct consequence of the poison of influenza, just as its poisonous influence upon the pneumogastric nerve has long been held to account for the frequent pneumonic congestion and the cardiac debility. The tumefaction of various lymphatic glands and of the spleen noted in many cases still further indicates the lymphatic apparatus as a chief seat of lesion.

I must therefore regard the immediate anatomico-pathological lesion of influenza, as manifested in the upper respiratory passages, as one involving the lymphatic organs and structures, in consequence of which the lymph accumulates in the connective tissue.

There appears to be a paresis of the nervous system, in partial result of which there is a stasis in the venous and lymphatic circulations. Hence passive sanguineous congestions, echy-moses, and hæmorrhages from the one, and passive lymphous congestions and lymphous or mucoid exudations from the other. Fibrinous exudation occurs in some instances, and a typhoid grade of inflammation in others, sometimes terminating in suppuration and in discrete or in diffuse abscess.

I have had two most remarkable instances of a happy effect of severe attacks of influenza upon malignant diseases. One was a severe case of epithelioma of the palate in a gentleman more than eighty years of age. The diagnosis had been confirmed by histological investigation. I had destroyed the entire disease upon one side by partial excision and by electrolysis, and it had cicatrized in the most satisfactory manner. The opposite side, which was not near as extensively diseased at first as the other side, resisted the same treatment and also the electric canterry. It had in places succumbed to lactic acid, but, despite all that could be done, the disease had extended to the pharyngopalatine folds and to the region of the alveoli, when, in January, 1891, the patient was suddenly attacked with the influenza. The brunt of the disease was borne in the epitheliomatous portion of his throat; the entire diseased portion sloughed out, and he convalesced from his influenza and his epithelioma together. A year later he called to pay me a Christmas visit, and he was so stout I did not recognize him until he laughingly recalled himself to me.

\* B. Fränkel. *Deut. med. Woch.*, No. 23, 1890.

† Krakauer. *Loc. cit.*

The other case was one of tuberculosis of the lungs and the larynx in a lady about fifty years of age. The cough was incessant. Rest at night could be secured but by spells, and that with difficulty. Expectoration was extreme. It was reported to me by her family physician as more than a pint in the twenty-four hours. This lady was attacked with influenza, and that disease cured her tuberculosis. She has not coughed or expectorated for eighteen months, and is, to all intents and purposes, a healthy, though not a robust, woman.

These cases present some compensation for the much larger class in which the influenza hurries the patient to his doom. They remind me very much of a number of cases which I have observed for many years in hospital practice, in which patients with tuberculosis, with syphilis, and with carcinoma have become cured by the effects of an intercurrent attack of erysipelas. I have been afraid to inoculate similar patients with erysipelas, lest it should get beyond control, for erysipelas of the nose and throat is a very serious disease; but I have again and again called the attention of some of my bacteriological friends to the importance of the subject, and have for years unavailably coaxed some of my surgical friends to have some of their cases of carcinoma of the mamma inoculated with erysipelas, as that disease would be more manageable on the exterior of the body than in its cavities.

I can thus confirm the observations recently recorded from various sources, that infection with erysipelas will sometimes cure tuberculosis and carcinoma.

THE RESULT OF  
TREATMENT OF THE UPPER AIR PASSAGES  
IN PRODUCING PERMANENT RELIEF IN ASTHMA.\*

BY FRANCKE H. BOSWORTH, M. D.

I THINK all of us will confess to a certain degree of enthusiasm in adopting new and original methods of treatment for the relief of hitherto obscure and intractable diseases, and, furthermore, that in recording our results we are under the influence of a certain mental bias, which leads us perhaps to overrate our successes. Whether this be true in regard to the intranasal treatment of asthma seems now the fitting time to decide, in view of the fact that a number of years have elapsed since the remarkable observations of Schäffer, Fränkel, Bresgen, Hack, Daly, Spencer, Todd, and others were first put on record.

In a paper read before the American Climatological Association on May 28, 1885, I advanced the theory that an asthmatic paroxysm is dependent on three conditions: First, a general neurotic habit; second, a diseased condition of the intranasal mucous membrane, and not the bronchial; and third, some obscure atmospheric condition; the former two being the active predisposing causes, while the latter is the exciting cause of the paroxysm. The truth of these propositions I think is generally accepted; certainly no one

will question at the present day the fact that a diseased condition of the nasal mucous membrane exerts a very marked influence in the production of a paroxysm of asthma. This being true, the further proposition must be accepted, that in the restoration of the nasal mucous membrane to a condition of healthy function we remove one of the very active causes of the asthmatic paroxysm, and thereby are notably aided in the complete cure of the disease. I should like, parenthetically, to emphasize this point, and repeat that our efforts in intranasal treatment should be directed broadly toward the complete restoration of healthy functional activity in the membrane, for I consider it as a somewhat narrow view to regard the removal of a simple nasal stenosis as the prominent indication.

In my former paper I furthermore argued that a paroxysm of asthma not only depended on the three stated conditions, but that the removal of any one of them, and not all, was ordinarily sufficient to arrest the disease. We all of us recognize the fact that a resort to certain elevated regions is almost invariably attended by immediate relief. In this way the obscure atmospheric condition which is the cause of the paroxysm is removed. We are furthermore familiar with the fact that in many instances where, by our general and specific therapeutic measures, the peculiar neurotic condition is overcome, the asthmatic paroxysms terminate. In the remaining cases of relief afforded by treating the intranasal condition, clinical observations have multiplied themselves to such an extent that the success of this method in a certain number of cases can not be questioned. The permanence of the results, however, opens up an exceedingly interesting and pertinent inquiry. In a paper on asthma, published in the *American Journal of the Medical Sciences*, in September, 1888, I analyzed the results of treatment in eighty cases, thirty-four of which were instances of hay-asthma or periodical asthma, and forty-six of perennial asthma or true nervous asthma, as it has been called. For our present purpose these may be grouped together. Of the eighty cases, I reported forty-six as having been cured, twenty-six improved, three unimproved, and in five cases the results were unrecorded. Three years have now elapsed since this record was made, and I regret exceedingly my inability to report as to the ultimate results of treatment in these cases. This report was based on a somewhat extensive correspondence, and the limited time at my disposal has prevented my hunting up the cases, the very large proportion of which have passed from my observation. A few of those patients who were reported as cured, however, have suffered relapses, but I am confident that I do not understate the number when I say that in but six of them have the asthmatic paroxysms returned, but of these the violence and frequency of the paroxysm in no instance equaled that which existed before the treatment.

Since this report I have recorded and subjected to treatment eighty-eight additional cases of asthma in which there was a co-existent intranasal lesion of a turgescient character. In running over these cases I find that forty-two patients were cured, thirty-three were improved, two were unimproved, and in eleven the results were unknown, the patients being seen usually but once. The local lesion was in the

\* Read before the American Laryngological Association at its thirteenth annual congress.

very large majority of instances either nasal polypi, deflected septum, or hypertrophic rhinitis.

Leaving out of consideration the eleven cases in which the results were unknown, we have seventy-seven patients suffering from some form of asthma, in only two of which did the intranasal treatment fail to afford a certain amount of relief. If this report is correct, and I believe it to be absolutely so, I think no stronger evidence could be adduced of the intimate and close causative relation which exists between a diseased condition of the nasal mucous membrane and asthma. Since Voltolini's first observation, I think no one denies that nasal polypi may be the cause of asthma, but hypertrophic rhinitis and deviations of the septum as a cause of the disease are still seriously questioned by many.

I have reported forty-two cases as cured. Curiously enough, there would seem to be some question as to what constitutes a cure in asthma. I think, however, that we are fully justified in considering a patient cured who has passed through twelve months of immunity, subjected as he is during that time to the various atmospheric changes which are so prone to give rise to an attack, especially during the cold and damp weather of the spring and fall months. In the foregoing report I have endeavored to confine myself to this rule, though in some of the cases the reports cover two and three years of immunity.

The thirty-three patients reported as improved include not only those in whom the paroxysms were notably mitigated, but others in whom months elapsed without an attack, and in many the disease had ceased to be a source of any very serious distress, and yet, the immunity not persisting for the full twelve months, I have recorded them simply as improved.

Coming now to the immediate topic of discussion—viz., the permanence of relief afforded by intranasal treatment—I think this is fully answered by this report. This method is clear in its indications, easy of accomplishment, and promises, I believe, not only more immediate relief, but more permanent relief from this distressing disease than any method of treatment yet suggested.

While, therefore, this method affords so much promise, for both the temporary and permanent relief of the disease, it is to be borne in mind that we are dealing here with but a single factor in its causation. The neurotic habit is an equally prominent factor, and I do not think we have done our full duty in any case without giving our patient the full benefit of those general hygienic measures, together with internal medication, which are attended with such excellent results in their action upon the nervous system.

THE SECOND YEAR'S WORK IN  
DISEASES OF THE RECTUM  
AT THE NEW YORK POST-GRADUATE HOSPITAL.

By CHARLES B. KELSEY, M. D.

At the end of this the second year of the clinic we will devote the hour to a short review of the work done, glancing back over cases, operations, and results grouped together.

During the year 1891 we have had one hundred and forty new cases, presenting one hundred and forty-seven distinct diseases. In these cases, seventy-four operations have been done before the class, which we shall speak of more in detail. These figures, added to those of the first year, give us as total for the two years and one month since the clinic was opened of two hundred and seventy-eight cases of disease and one hundred and forty-one operations in public. When this opportunity for seeing diseases of the rectum is compared with what existed before the establishment of the clinic, we can only congratulate ourselves and thank the profession at large for sending the material.

Of the cases treated during the past year many have been of great interest. Our mortality during the first year came from hopeless cases; this year it has illustrated the risks of even trivial operations. There have been three deaths. One was that of an apparently strong man—but, it appeared afterward, a hard drinker—due to diffuse, septic, pelvic cellulitis following the opening of a small abscess in the perinæum. Another was caused by acute alcoholism, following an operation for fissure upon a drunkard, who had to be removed to Bellevue the following morning; and the third was from a very extensive extirpation. The patient had previously been colotomized to make the operation by Kraske's method as safe as possible, and had we stopped there he would be alive now. The case seemed a suitable one for extirpation until it was too late to abandon the operation, but the shock was too great. It was one of those to which the recently coined word "inoperable" particularly applies.

Looking back over our cases, there is one which I think is unique. It is well known that a congenital stricture of the rectum which during early life has caused comparatively few symptoms may, as age advances, cause greater annoyance and danger from the loss of suppleness in the parts, and the final addition of ulceration to the other conditions. No case has ever come within the range of my reading, however, where such a congenital stricture first made itself known by complete intestinal obstruction at the age of thirty-five. The patient was a colored woman, under the care of Dr. H. L. Richardson, of New York.

On questioning, she said she had noticed that never in her life had her passages been larger than the little finger, but she supposed that was natural and had never had any sickness. At the usual site of such strictures, just fairly above the sphincters, about two inches from the anus, there was found a perfectly characteristic membranous obstruction with a pin-head perforation. The opening, which had been sufficient for thirty-five years, had become contracted from thickening and inflammation, and would no longer allow the escape of feces. Above the first membrane there was a distinct congenital narrowing of the gut, but not to a degree to cause any obstruction. The membrane was freely divided, the obstruction was relieved, and the patient left the hospital in a week.

The capital operations for cancerous and non-malignant strictures have done well. There have been fourteen colotomies, four complete extirpations, and three proctotomies with but one death—that already referred to. But few comparatively of our cancerous strictures have been when first seen at a stage which rendered extirpation justifiable, and

hence the number of colotomies. The rule in operating has been that a cancer that was movable could be extirpated, while one that was firmly attached to neighboring parts should be treated by colotomy. The trouble with the results of extirpation comes from the lack of room to get clear of the disease in many cases. In cancer of the breast we cut clear of the disease with an ample margin, while in cancer of the rectum we dissect the disease carefully off from the prostate, the base of the bladder, the vagina, and the uterus with no margin whatever. In many cases the growth is only just removed, if indeed it is entirely removed, and it is not strange that there should be quick recurrence.

Of the results of the colotomies it is impossible to speak too highly. In none have we failed to give great relief to suffering, and in none to gain a considerable length of life over what the patient would have had without the operation. This you have all had a chance to see for yourselves, not only in the cases operated upon this year, but in those of longer standing in which the patients report occasionally. There are few of you who do not come here with your minds possessed of the natural and general antipathy to this method of prolonging life and relieving suffering, but none of you carry that feeling away with you after coming in personal contact with those who have been operated upon. Instead of a lot of miserable, loathsome creatures, "better dead than alive," you find a very jolly and contented class of patients, male and female, married and single, attending to the ordinary duties of life, none of whom could under any circumstances be induced to change their present condition for that before the operation.

If this clinic never does anything more than to overcome the ignorant prejudice against this operation and bring this remedy into universal repute for proper cases, as the similar clinics have done in England, it will still have justified its existence.

And yet we are very conservative in recommending and practicing colotomy. It is never done where anything else will give relief that is not attended by too great risk. Cancers we extirpate if we can, and non-malignant strictures we treat in every other way likely to do good, including also extirpation, before doing colotomy. But in all cancers we either extirpate or perform colotomy as soon as the patient's consent is gained. Nothing can be gained and life may be lost by delay. And so in the non-malignant cases, where complete extirpation of the disease is out of the question, and where divulsion, division, and dilatation have been tried for years; where acids and injections and suppositories have been kept up till the patient is discouraged, and he is steadily losing ground, we do not wait long before relieving him after we decide that all other treatment is worse than useless.

It is well to impress this upon you again, for the idea seems to have gone abroad that we do colotomies here in preference to other modes of treatment. The fact is that we never do colotomies except to prolong life when no other mode of treatment is applicable; and that if we did not give relief in this way these patients would simply be sent away to continue their sufferings and die a miserable death. This is why I am always trying to impress upon

you that it is more important to know when to do a colotomy than how to do a colotomy, and why I never do one without asking several of you to come down into the amphitheatre and tell the class what other plan of treatment is applicable. In cancer you suggest extirpation, and I explain to you that the disease is not suitable for extirpation, being too extensive and attended by too great a risk to life. In non-malignant disease you suggest all the recognized modes of treatment, and it is answered that all have been tried without benefit, and from the extent of the disease none can be of benefit; and thus in every case, having eliminated every other proper mode of treatment, I try to convince you that colotomy should be done, and the results you see.

Perhaps the best argument in favor of the operation that can be given you is that twice a patient operated upon has, after a time, brought us a friend suffering in the same way who desired the same treatment.

The cases in which colotomy has been performed illustrate many forms of disease for which the operation is indicated. Six were for cancer too extensive for removal; three for extensive and incurable non-malignant ulceration and stricture; two in women for chronic intestinal obstruction due to old pelvic exudation; and one as a preliminary to a subsequent extirpation by Kraske's method.

In the matter of our fifty cases of piles and twenty operations with the clamp and cautery we have done well, having had nothing but the most satisfactory results. In the one case in which we yielded to the continual demand of the students from the West to know about carbolic-acid injections, we were more than usually unfortunate.

The man was in fairly good condition, "could not be operated upon," and was bleeding profusely, and the students wanted to see the carbolic-acid treatment. Now you all know that I consider this one of the most uncertain of all treatments, but in this particular case I tried it for the benefit of the class. A moderate-sized tumor was injected with five drops of a thirty-three-per-cent. solution of carbolic acid in equal parts of glycerin and water. The patient felt no pain at the time and was told to come again in a week if he had no trouble, but to report in forty-eight hours if anything went wrong. In forty-eight hours he reported. On the side where the injection had been made there was a marginal tumor of the size of a horse-chestnut covered with equal parts of skin and mucous membrane, and with the mucous membrane gangrenous and sloughing. On the opposite side, where no injection had been made, there was another tumor outside the anus and irreducible, almost of the size of the former. The first one sloughed and shriveled, the second suppurated and burst with two openings—one on the skin and the other on the mucous membrane. The patient was in bed three weeks, and they tell me went away thinking he had been very fortunate in finding a doctor who could cure piles without an operation.

This was an unfortunate result. In the vast majority of cases the treatment would have been satisfactory. It is just such exceptions as this that have led me to abandon it, and everybody who practices the method for any length of time will occasionally have just such a case.

By the courtesy of Dr. Boldt we have been able to show you at St. Mark's Hospital two very rare cases. The first was a typical case of chancroidal ulceration around the

anus and within the rectum, one of the cases that prove indubitably the occasional causation of so-called syphilitic stricture by chaneroid, and go to the support of the classical argument of Mason, many years ago, that most of the "syphilitic strictures" were not syphilitic but chaneroidal. You will seldom have a chance to see the causation and follow the development of venereal stricture as in this case.

The other case of Dr. Boldt's was one of sarcoma of the sacrum, causing a distinct tumor in the soft tissues over the sacrum, and another, of the size of an egg, projecting into and partially occluding the rectum—a case, perhaps, ultimately for a colotomy should the new growth advance on the rectal side sufficiently to cause obstruction. In one of my first colotomies complete obstruction was caused by a growth of this kind from the promontory of the sacrum, which first manifested its presence by causing the usual symptoms of acute intestinal obstruction.

Another rare case was that of the physician who complained of congenital absence of controlling power in the sphincters. Fluid passages were always liable to escape him without notice, and flatus did the same. We tried to tighten the orifice with the Paquelin cautery, but the patient has written me since that the operation was a failure—a statement that, for certain reasons, I am not quite prepared to accept.

The remaining cases need no special comment. The fissures, fistulæ, abscesses, both superficial and deep, the cases of intestinal catarrh and of actual ulceration of the rectum, need not be dwelt upon. Our object has been to give a brief *résumé* of the work done and the results.

## THE OFFICE OF CORONER IN NEW YORK.\*

BY WOOSTER BEACH, M. D.

THE office of coroner in this city is filled by four men elected on the county ticket, whose term of office is three years.

Each coroner appoints a physician who acts as his assistant at inquests and makes examinations of all dead bodies, post-mortems should he deem them necessary. Besides these officials, there is a clerk connected with the office whose duty it is to receive the reports of cases requiring attention and keep a record of the inquests. He also attends to the proceedings in suits in which the sheriff is a party—almost exclusively cases where property is replevined from the sheriff.

The usual daily routine of the coroner's office is about as follows: The cases from the various parts of the city requiring the attention of the coroner during the day are reported to the clerk mostly by the police, under whose notice they generally first come.

Unless the case is known to be of more importance than usual, the practice is for the coroner's physician to proceed to the place where the body lies, examine it, take the state-

ments of one or more witnesses as to the manner of death, and furnish a certificate for burial.

In the important, or at least the prominent, cases the coroner accompanies the physician in his visit to the body, and then the formal proceedings as prescribed by the law are more nearly followed.

The inquests, so called, containing the statements of the witnesses taken by the physician alone are completed at uncertain intervals when a sufficiently large batch has accumulated. This is done at the office by the coroner swearing a jury, who finish up the dozen or more papers on hand by affixing their signatures to them. This wholesale manufacture of inquests is certainly not legal, but, in view of the unimportant character of the cases acted upon, it is perhaps allowable.

The number of cases reported at the coroner's office in a day runs from five to ten. One may be an accident, one a suicide, one a case of drowning, and perhaps one of murder. It may be that an ante-mortem examination may be required. By far the larger number reported are of persons dying without medical attendance, and consequently, as no certificate of burial has been given, one must be obtained from the coroner.

The average time required for holding an inquest is less than half an hour. A few cases may consume an entire day or more, but, taking them altogether, the above-stated will be about the average time. As the work is divided among four coroners, it will be seen that their labors can not be deemed onerous.

For the entire expense of the coroner's department \$52,000 per annum is appropriated.

The defects in the present system are:

1. The choice of the coroner by election. It is scarcely necessary to refer to the evils of this defect to a citizen of our city. The practical working of this plan is that the office is filled by a man totally ignorant of the duties required of him, and quite likely not to trouble himself about them during his term of office.

2. The coroner's jury. Except, perhaps, in a few cases, there is no necessity for such a body. If a coroner's case results in a conviction of a criminal, it subsequently comes before two juries—the grand and petty.

3. In the case of persons dying unattended by a physician, or where there is no suspicion of crime connected with the death, the entire formality of a coroner's inquest is required for no other object than that of obtaining a certificate for burial.

4. If the coroner himself knows little or nothing of the duties required of him, we can not reasonably expect that he will choose a proper medical assistant. We may consider ourselves fortunate in this city that we have physicians in good standing as appointees.

5. The costs of the coroner's department are excessive. Really good service should not cost one quarter of the amount paid.

In any attempt at reform in the coroner's office the importance of the medical service must be kept prominently in view.

The examination of the dead body in criminal cases far

\* Read before the Section in Public Health and Hygiene of the New York Academy of Medicine.

exceeds in importance any other proceeding connected with the coroner's investigation. The coroner may bungle, but his actions may be reviewed and corrected. Not so with the post-mortem examination of the body. Its position, its surroundings, may, to a trained eye, furnish most important evidence which, not taken advantage of before it is disturbed, may be lost forever. With the dissection it may be even worse. The scalpel of the incompetent physician may make sad havoc with wounded or diseased organs and entirely destroy evidence that a proper examination would reveal.

An autopsy, therefore, made in an unskillful manner may actually be the means of covering up a crime instead of bringing it to light.

In 1877 a law was passed in Massachusetts abolishing the office of coroner and the coroner's jury, and substituting "medical examiners" in their place.

That law has secured good results and works smoothly. With some changes it would be suitable for New York, but in our State the election of a coroner in each county is made obligatory by the Constitution, and it is only by a constitutional amendment that the office can be abolished. Still, the Legislature may limit the powers or change the duties of the coroner and provide for the appointment of medical examiners, so as to get substantially the same law as that of Massachusetts. In that State the legal part of the investigation is taken charge of by a *trial justice*, assisted, if necessary, by the district attorney. By the New York Legislature granting the powers of the Massachusetts *trial justice* to our coroner, the obstacle presented by the Constitution may be overcome.

The really great difficulty in effecting the reform we desire is in securing the appointment of the proper man for a medical officer and in keeping the office free from political influence. No matter how perfect a law we may have, if the most careful discrimination is not exercised in selecting a man to carry out its provisions, it will be a failure.

Nothing, then, should engage our deliberations more earnestly in forming a plan to carry out our object than the selection of the proper appointing power that is to furnish us with the medical examiner.

The Section in Gynecology and Abdominal Surgery of the Pan-American Medical Congress has been organized by the election of Dr. William Warren Potter, of Buffalo, as executive chairman; Dr. Brooks H. Wells, of New York, as English-speaking secretary; and Dr. Ernst W. Cushing, of Boston, as Spanish-speaking secretary. The foreign secretaries of the section thus far elected are: *The Argentine*, Dr. Dn. L. C. Maglioni Llobet, Victoria 737, Buenos Aires; *Brazil*, Dr. Dm. Luiz da Cunha Feibo, Rio de Janeiro; *British North America*, Dr. J. F. W. Ross, Esq., Toronto; *United States of Colombia*, Dr. Dn. José M. Buendia, Calle 10, No. 212, Bogotá; *Nicaragua*, Dr. Juan I. Urtecho, Calle Real, ciudad Granada; *Spanish West Indies*, Dr. Dn. Gabriel Casuso, Virtudes 37, Habana, Cuba; *Uruguay*, Dr. Dn. Enrique Peréy, Uruguay 371, Montevideo.

A Death following the Administration of Chloroform has occurred in New York during the past week. The patient was an old man with atheromatous arteries, in whom an amputation for gangrene of a finger was about to be performed. The anæsthetist had had two years' experience in hospitals in the city, and the coroner's inquest showed that the patient's death had been caused by pulmonary œdema.

NEW YORK, SATURDAY, MARCH 26, 1892.

REFORMS NEEDED IN NEW YORK CITY INSANE ASYLUMS.

RECENTLY the Mayor of New York appointed a commission of five well-known gentlemen to investigate the subject of the care of the insane in the city asylums, and to report whether it was advisable to continue the present system or to turn the patients over to the State.

The commission has just made its report, and those unfamiliar with the condition of these municipal institutions will probably turn it over to see if their eyes did not deceive them, and if some other place than New York city is the subject of the report. That the commission did not favor the transfer of both patients and institutions to the State is probably because they believe atonement should be made in the future for the sins of the past. For no other reason is it apparent that what they characterize as "a reproach to humanity" should be continued, even upon the plea that the city recognizes the curability of insanity. From their inspection of both State and city institutions they found the latter superior to the former in one particular—that of furnishing iron bedsteads! Were it not for the importance of the subject and the wretched condition of affairs that is now brought prominently before the public it might be imagined that the commissioners had desired to instill some humor into their report. And, yet, read their presentment: "The condition of these insane poor is pitiable. Their accommodations are a reproach to humanity. Overcrowding exists in every building of every department, and their wretched existence is rendered still more intolerable by the absence of comfortable surroundings, of proper accommodations of every kind, and by insufficient protection in the case of many of the smaller buildings from the inclemency of the weather. There is also the danger of fire, which, in the inflammable wooden buildings, would be certain to result in large loss of life." If these unfortunates were convicts their environment would be better.

On January 30, 1892, there were 5,485 insane patients in the asylums on Blackwell's Island, Ward's Island, and Hart's Island, and at Central Islip, and the total cost of maintaining these institutions during the year was about \$700,000. In the seven State hospitals there were 5,870 inmates, and they cost \$1,100,000 annually to maintain. In other words, this city is attempting to care for almost as many insane patients as the State in half the number of buildings and at two thirds of the cost.

For the relief of the existing evils it is recommended that the per capita allowance for the support of the insane be increased; that they should be removed from the neighborhood

of convicts and paupers; that the quality of the food should be improved; that the medical superintendent should have full authority over his subordinates; that the old buildings should be replaced by better ones; and that some of the present buildings should be enlarged. For the sake of our reputation for humanity alone, it is to be hoped that these necessary changes will be inaugurated at an early date.

#### THE DIAGNOSIS OF DRUNKENNESS.

A LECTURE delivered before the Hunterian Society of London by Dr. J. Hughlings Jackson, entitled *Neurological Fragments*, was published in the *Lancet* for March 5th. The lecture bristles with ingenious suggestions, but, on account of certain peculiar terms coined by the author and on account of his brevity of expression, parts of it require careful and repeated reading to bring out their full meaning. In our last issue we mentioned his remarks on the reflexes in connection with the condition of supervenosity; another matter on which he spoke very instructively was the difficulty sometimes felt in diagnosing drunkenness in the absence of a history of the onset of the symptoms.

For practical purposes, he said, alcoholic intoxication had to be studied carefully. It was well known that men fatally ill from cerebral lesions were sometimes locked up in police cells for drunkenness, and it needed to be insisted on that intracranial lesions that would soon result in death might give rise not only to insensibility, but also to the manner and conduct of a person partly intoxicated with alcohol. He alluded to a fatal case of meningeal hæmorrhage in which the patient was violent and profane and, what was more striking, showed purposive action. On the other hand, men were sometimes seen in the hospital who, after sucking raw spirits out of a cask, were seemingly in a state of coma as deep as that caused in other men by a large and fatal cerebral hæmorrhage. Without the history of the circumstances and of the mode of onset, the diagnosis of apoplexy produced by alcohol from that produced by cerebral hæmorrhage was very difficult and might be impossible; for an hour or two after an injury to the head there might be a condition very like that of a man slightly drunk, and the patient might act elaborately even if foolishly, while "unconscious"—unconscious in the sense that on his recovery he would remember nothing of his strange doings.

When a man of Hughlings Jackson's rare acumen in diagnosis makes such statements as these, it seems as if the wisecracks of the daily newspapers might with propriety curb the glibness of their criticism of the occasional ambulance surgeon who makes a mistake.

#### MINOR PARAGRAPHS.

##### THE QUESTION OF THE CONTAGIOUSNESS OF LEPROSY.

IN the March number of the *International Medical Magazine* Dr. L. Duncan Bulkley concludes a paper with the statement that there is no warrant for the popular terror at the name of leprosy as a disease; that, while probably of bacillary origin,

it is not contagious in the ordinary acceptation of the term. When acquired, the disease may, under favorable conditions, be transferred from one person to another; and, while heredity may account for a share of the cases, the disease is not necessarily so transmitted. Furthermore, there is far greater reason for the restriction of syphilitic and tuberculous persons by isolation and segregation than for that of lepers. This opinion of an American dermatologist is fortified by the recent report of the English Leprosy Commission, in which their study of the disease showed that it was contagious and inoculable only in a very limited degree and not hereditary. They found only half as many cases of the disease in India as had been estimated. As a result of two thousand experiments, the commission considered the risk of inoculation so small that it might be disregarded, and concluded that a fish diet had nothing to do with the disease.

##### SUPPLIES FOR THE MEDICAL CORPS OF THE ARMY.

AN awkward impediment to the work of providing the medical staff of the army with certain necessary supplies for which a contract had been given out seems to have come up in the shape of a criticism by the Second Controller of the course pursued by the Surgeon-General in the matter. It appears that after the contract had been made it became evident that certain modifications of the articles contracted for would render them decidedly more useful, but that the changes would entail a moderate advance on the prices agreed upon. The Surgeon-General thought it proper to change the contract accordingly without going to the additional expense of publishing a fresh invitation for bidders. As the newspapers have it, he has done so, and will leave the question of irregularity to be settled in the future. This degree of latitude, it seems to us, might well be allowed to the discretion of the head of a staff department.

##### GUNSHOT WOUNDS OF THE SPINAL CORD.

IN the February number of the *Revue de chirurgie* there is an exhaustive article on this subject by Dr. E. Vincent. M. Vincent's conclusions are as follows: These injuries are of great gravity, but they are not necessarily fatal, and there is reason to believe that surgical intervention may help to save some of the wounded. Whatever may be the nature of the injury to the spinal cord—provided there is no mortal injury of a thoracic or abdominal organ, and provided the wound involves the posterior or lateral portion of the vertebral column at an accessible point—the tract of the wound should be enlarged and any foreign body that may be found should be extracted, and for this purpose one should not hesitate to open into the rachidian canal if necessary, for such a procedure, although sometimes futile, is harmless, with antiseptic precautions, and may prove of advantage.

##### THE ASSOCIATION OF THE ALUMNI OF THE NEW YORK HOSPITAL.

ON Wednesday evening of this week a meeting of ex-members of the house staff of the hospital and its branches was held in the governors' room for the purpose of organizing an association having the title that heads this article. It was well attended, and a number of letters and telegraphic messages were read from gentlemen who were unable to be present, all of whom expressed their hearty sympathy with the undertaking and their readiness to take part in it. It is strange that such an association was not formed many years ago, and the older graduates of the hospital are undoubtedly glad that the superior enterprise of their younger brethren—especially of a committee

consisting of Dr. Walter Vought, Dr. E. W. Clark, and Dr. T. S. Southworth—has at last made its organization an accomplished fact.

#### A MAGNETIC PHASEMETER.

In the March number of the *American Journal of Science* Mr. John Trowbridge describes an instrument adopted by him for use in determining questions of the phase of alternating electric currents in transformers and in branch circuits. Two telephone diaphragms are provided with mirrors, and a beam of light is reflected in such a manner that the vibration of one diaphragm gives a spot of light a horizontal motion, the other one gives the spot of light a vertical motion, and the combination of the movements gives a figure that indicates the relative amplitude of the motions of the diaphragms and also the difference of phase of the currents that set the diaphragms in motion. This device Mr. Trowbridge calls a phasemeter.

#### AN UNJUST AWARD IN A MALPRACTICE SUIT.

A JURY in Poughkeepsie has recently rendered a verdict of \$2,500 against a physician of that city for alleged malpractice in the case of a man who fell upon a sidewalk of dirt and ashes and sustained a compound, comminuted fracture of the arm. A month after the accident he was admitted into St. Luke's Hospital, New York, for septic infection, the arm was incised to facilitate the escape of pus, and it has been useless since he recovered. He bases his suit on the ground that the attending physician at his home did not properly cleanse the wound. The award on this ground seems to us to be very unjust, as the most skillful surgeon might, under the circumstances, have had a similar result.

#### ANKYLOSTOMIASIS THE BERIBERI OF ASSAM.

ACCORDING to the *Indian Medical Gazette* for February, 1892, Dr. G. M. Giles finds that the diseases known as the beriberi and the kala-azar of Assam are identical, and that they are in reality ankylostomiasis caused by the *Dochmius duodenalis*. This parasite, Dr. Giles finds, develops slowly if at all in drinking-water, but develops plentifully in feces. The ingress of the parasite into the human system is believed to be due to the habit of cleansing kitchen and table utensils with infected earth, and of eating food from a mat on the ground. The symptoms and causation of the disease are the same as those found by Dr. Kynsey in the so-called beriberi of Ceylon.

#### THE VALUE OF ALBUMINURIA AS A MEANS OF DIAGNOSIS.

In a paper on this subject in the *International Medical Magazine* Dr. F. R. Sturgis, of New York, concludes from a survey of the literature that albumin in the urine does not necessarily signify any renal disease; that it exists temporarily in many diseases unassociated with any organic renal complication; that from the uncertainty of tests and methods of testing it loses a great deal of its value as a diagnostic sign; and that if present in even a small quantity it is a danger-signal, and if persistent indicates some serious organic lesion.

#### ANTE-MORTEM BURIAL.

OUR excellent contemporary the *Maryland Medical Journal* publishes in its issue for March 19th a very useful article entitled Studies in Plaster Jackets and how to make Removable Plaster-of-Paris Corsets, by Dr. C. C. Barnwell, of Baltimore.

The secondary title of Dr. Barnwell's article is: "After the Method of the late Professor Louis A. Sayre, M. D., of New York," meaning undoubtedly Professor Louis A. Sayre, who, we are glad to be able to say, is still in the flesh and shows no signs of hastening to put on immortality.

#### PROMOTION EXAMINATIONS IN THE ARMY MEDICAL CORPS.

By a recent law no medical officer in the army can be promoted to the rank of captain until he has passed an examination for promotion. Heretofore the medical officers of the army have been promoted to the rank referred to at the end of five years' service without an examination, while their less favored brethren of the navy and of the marine-hospital service have had to prepare at the end of three and four years' service, respectively, for an examination preliminary to promotion that was quite as rigorous as that given for admission into the corps.

#### NEW TITLES FOR ARMY MEDICAL OFFICERS.

THE Senate has just passed a law giving to officers of the medical corps holding the rank of colonel the grade of assistant surgeon-generals, and to those holding the rank of lieutenant-colonel the grade of deputy surgeon-generals. These are new titles in our army and are similar to those of the British army medical corps.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending March 22, 1892:

DISEASES.	Week ending Mar. 15		Week ending Mar. 22.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	4	12	2	6
Typhoid fever.....	7	2	9	6
Scarlet fever.....	231	31	215	28
Cerebro-spinal meningitis.....	0	0	4	4
Measles.....	328	20	282	23
Diphtheria.....	98	32	109	37
Small-pox.....	1	1	4	1
Erysipelas.....	0	0	2	0
Varicella.....	0	0	10	0
Pertussis.....	0	0	2	3
Mumps.....	0	0	2	0

**A Bacteriological Institute in Tokio.**—Dr. Kitasato, who has been in Koch's laboratory for many years, and who is so well known for his bacteriological researches, intends to leave Berlin to open a bacteriological institute in Tokio.

**Changes of Address.**—Dr. William R. Ballou, from New York to the Oakland Heights Sanatorium, Asheville, N. C.; Dr. F. J. Leviser, to No. 640 Madison Avenue.

**The Sixth Annual State Sanitary Convention of Pennsylvania,** under the auspices of the State Board of Health, will be held at Erie on the 29th, 30th, and 31st inst.

**The New York Post-graduate Clinical Society.**—The special order for the meeting of Saturday evening, the 19th inst., was a paper entitled Points in the Diagnosis and Management of Serous and Suppurative Pleurisy, by Dr. J. K. Crook.

**A Society for the Promotion of Maternal Lactation** has been organized in Paris, according to the *Gazette hebdomadaire de médecine et de chirurgie*.

**The Death of Dr. D. Hayes Agnew, of Philadelphia,** occurred, not unexpectedly, on Tuesday of this week. He was in the seventy-fourth year of his age. He obtained his medical education at the University of Pennsylvania, and in his later years was professor of surgery in that

institution, having in the mean time won distinction as a teacher of anatomy in the Philadelphia School of Anatomy. He was a surgeon of distinction and the author of a well-known text-book of surgery.

**The Death of Dr. H. Rosenthal, of Berlin,** for many years the editor of the *Allgemeine medicinische Central-Zeitung*, is announced in the *Wiener klinische Wochenschrift* as having taken place recently.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending March 19, 1892:*

- MARSTELLER, E. H., Passed Assistant Surgeon. Ordered to duty at the Naval Academy.
- ARNOLD, W. F., Passed Assistant Surgeon. Detached from the Vermont and ordered to the Richmond.
- LOWNDES, C. H. T., Assistant Surgeon. Detached from the Richmond and ordered to the Vermont.
- DICKINSON, D., Surgeon. Detached from the Navy Yard, Mare Island, and granted two months' leave.
- MOORE, A. M., Surgeon. Detached from the Naval Hospital, Mare Island, and ordered to the Navy Yard, Mare Island.
- NORFLEET, E., Surgeon. Detached from the U. S. Steamer Monocacy and granted three months' sick leave.
- SMITH, G. T., Assistant Surgeon. Detached from the U. S. Steamer Mohican and ordered to the U. S. Steamer Hassler.
- YOUNG, L. L., Assistant Surgeon. Detached from the Independence and ordered to the Mohican.
- SCHOFIELD, W. K., Medical Director. Granted one year's leave of absence, with permission to leave the United States.

**Society Meetings for the Coming Week:**

- TUESDAY, *March 29th:* Boston Society of Medical Sciences (private).
- WEDNESDAY, *March 30th:* Auburn, N. Y., City Medical Association; Berkshire, Mass., District Medical Society (Pittsfield).
- FRIDAY, *April 1st:* Practitioners' Society of New York (private); Baltimore Clinical Society.
- SATURDAY, *April 2d:* Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

**Answers to Correspondents:**

*No. 375.*—We can not answer your first question. In regard to the luminous signs, address Messrs. F. W. Devoe & Co., corner of Fulton and William Streets, New York.

*No. 376.*—The surgeon-general of the State of New York is Dr. Joseph D. Bryant, and his address is No. 54 West Thirty-sixth Street, New York city. Probably he can furnish you with information concerning the ambulance service.

Letters to the Editor.

COCAINE POISONING.

ANN ARBOR, MICH., *February 8, 1892.*

*To the Editor of the New York Medical Journal:*

SIR: Will you please grant me a short space in the *Journal* in which to record the phenomena accompanying a case of cocaine poisoning which recently came to my notice, and also the results of treatment? The patient is a young man who for some time past had been suffering from rectal ulcer with colitis accompanied with quite intense tenesmus, for the relief of which latter he had resorted to cocaine. On the afternoon of February 4th, upon his own responsibility, he took a suppository containing rather more than three grains of the drug. I saw him about an hour after and found his condition as follows: Pulse 150, thready; respirations 5 to the minute and simulating the Cheyne-Stokes variety; pupils dilated; bilateral sweating; surface cold, patient conscious, and responding well to questions; vision good; no pain; no nausea; surface

anæmic. I ordered twenty drops of tincture of digitalis with  $\frac{1}{6}$  of a grain of atropine sulphate hypodermically, to be repeated in twenty minutes; hot applications to the surface and brandy internally. Half an hour after the second hypodermic the patient's pulse had fallen to 120; the respirations had increased to 12 and were regular; and the surface was becoming warm and somewhat flushed. I then put him upon digitalis and strophanthus, three drops of each, internally, and omitted the atropine.

At midnight his pulse had reached 100, and the respirations were normal. From this time he rapidly recovered.

In two cases elsewhere reported I obtained similar results from the treatment pursued in this case. While digitalis, or any of the other cardiac tonics, is strongly indicated in these cases, there might be a question about the atropine, since the action upon the pupil of both cocaine and atropine is mydriatic, and this would indicate that the two agents are synergists. Yet cocaine paralyzes respiration, while atropine stimulates the respiratory function. Here, it would seem, is the chief indication for atropine to overcome the toxic action of cocaine. While this is true, yet it must not be forgotten that atropine also stimulates all the vaso-motor ganglia, and, if carried beyond a certain limit, would overcome the cardiac inhibition obtained by the digitalis—an important factor in eliminating the cocaine poison.

J. A. WESSINGER, M. D.

BEARD AND ROCKWELL ON ELECTRICITY.

NEW YORK, *March 14, 1892.*

*To the Editor of the New York Medical Journal:*

SIR: In a recent number of this journal a short review of the eighth edition of Beard and Rockwell's *Medical and Surgical Electricity* appeared in which defects were pointed out, while its merits were by no means overlooked.

The animus of the review was everything that could be desired. Certainly no author can complain when his book, after nearly two decades of uninterrupted success, is characterized as "deserving its popularity." But there is one statement to which I must demur.

The reviewer says: "Dr. Rockwell would inspire more confidence if he told us candidly that there were some infirmities in which electricity was of no use."

Now, at first sight this seems to be a very severe arraignment, but that the writer did not mean to convey any impression specially derogatory is evidenced by the general tenor of his remarks.

The truth might perhaps be more nearly stated if he would accept a mean between another review written by the late Dr. Frank H. Hamilton some years ago and his own. Dr. Hamilton stated that the book seemed to be given up to a discussion of what electricity would not do rather than what it would do.

How shall we reconcile two such divergent opinions emanating from fair and honest critics? A close inspection of the detailed cases (which in some future edition I hope to entirely recast) will clearly show that they are neither given up to "demonstration of what electricity will not do," nor to assertions that it is a universal panacea. No one better than he who has labored for years in the department of electro-therapeutics appreciates its limitations, and I can in a measure sympathize with the remark once made to me by Dr. E. L. Keyes, that he had "broken his heart over electricity." Now, among these cases many recoveries in many different conditions are very properly reported; but a careful perusal of the clinical portion of the work will show that a large proportion of cases are spoken of as only improved or relieved, while others relapsed, and not a few are recorded as receiving no benefit.

When electricity first came into prominence, some twenty years ago, it was earnestly hoped that electrolysis could be made to accomplish something for the relief and cure of cancer. In connection with Dr. Beard, I treated a very large number of cases of scirrhus of the breast and other parts, and indeed almost every variety of malignant growth. The most grateful relief of pain was often demonstrated, but it was just as clearly demonstrated then, and by subsequent efforts, that electricity was incapable to any extent of favorably influencing the progress of these scirrhus tumors of the breast. This and many other things equally unfavorable to electricity the book states clearly enough; and if the writer had done no more than to demonstrate this one fact, in the face of certain well-remembered statements to the contrary, he would regard it as sufficient to justify all the attention given to this department of medicine.

A. D. ROCKWELL, M. D.

## Proceedings of Societies.

### AMERICAN LARYNGOLOGICAL ASSOCIATION.

*Thirteenth Annual Congress, held at Washington, on Tuesday, Wednesday, and Thursday, September 22, 23, and 24, 1891.*

The President, Dr. W. C. GLASGOW, of St. Louis, in the Chair.

(Continued from page 329.)

**The Radical Treatment of Nasal Myxomata.**—Dr. W. E. CASSELBERRY read a paper on this subject. (See vol. liv, page 533.)

Dr. SAJOUS: I have listened with great interest to this communication; it is on a subject to which I have given much attention. I agree with the authors whom he quotes as to the difficulty of reaching the points from which polypi arise after removal of the growths. It is surprising to see how easy the operation seems to be as described in the books, but it is not so easy in practice. Some years ago I attempted to pass a galvano-cautery wire as far as possible behind the middle turbinated bone; I subsequently found that by using a rongeur forceps and removing a small portion of the middle turbinated bone at its anterior angle I made a convenient passage for the introduction of the instrument. I have not found it necessary, except in very few cases, to remove the whole body, in order to introduce the forceps or galvano-cautery. In applying the galvano-cautery, I have been much helped by using an electrode with a tip bent in the shape of a cirette. By not heating the wire too much, say to a red heat, it retains its hardness, and can be used as a cirette, combining the heat with the scraping of the surface, if so desired. The electrode I now show you is, as you can see, glass-covered. It can be easily cleansed and does away with the silk-covered electrodes, which can never be made absolutely aseptic. The glass electrodes are not affected by the heat of the incandescent tip.

Dr. J. SOLIS-COHEN: I rise simply to say that some months ago I read in one of the journals an article by a gentleman whose name I can not recall, in which he recommended, after removal of polypi, simply washing out the nose with a solution of alcohol or of witch-hazel. I would here bear testimony to its value; I use it in preference to the cautery. I use it in the strength of one to four, one to three, or even one to two—simply the distilled extract of hamamelis with alcohol.

Dr. BOSWORTH: I should like to ask if Dr. Cohen thinks that it will have the slightest effect in preventing the return of the polyp.

Dr. COHEN: Yes, I have found it so.

Dr. BOSWORTH: I have used both the witch-hazel and the cautery, and found neither of value.

Dr. COHEN: I use it in place of the application of the cautery, using injections twice a day; the patient can do this for himself.

Dr. BOSWORTH: I quite agree with the remarks which have been made with regard to the galvano-cautery. I think that it is the removal of the polyp which cures the patient; I do not think that there is any use in applying the galvano-cautery afterward unless some better reason can be given than has been offered. The principal value of the hamamelis in such cases is that it may prevent the use of something worse.

Dr. ROE: I agree with the last speaker, that the success of the treatment of nasal polyps lies in the completeness of their removal; but in some cases, owing to their situation, complete removal is well-nigh impossible. In the majority of these cases it is because the polyps lie behind an enlarged middle turbinated body. In all such cases in which the turbinated body is very much enlarged, and particularly where the bone is sufficiently projecting to press against the septum, I have made it a rule to remove a part of this projecting turbinated body. I do not remove the whole of it, but only sufficient to get at the base of the polyps. The method I adopt for its removal is by means of a saw, such as I presented to this association two years ago, and termed the nasal bow saw. It is modeled on the plan of the jeweler's saw, and by using one with the blade set at a right angle with the back and with a bow at the proper height, the amount taken off can be so accurately regulated that we can remove just the amount desired. I formerly used scissors, but scissors crush the bone before cutting it, and the same objection applies to the snare. I find the method that I have described by far the best, and it leaves the parts in a better condition for healing. In those cases where the base of the polyp is accessible I have for some time adopted a plan of encircling the polyp with the wire, and then dissecting away the base with a small knife, taking the periosteum with it; and where it is located upon a turbinated bone, taking off a small spiculum of bone with it. When this is done I never have a recurrence of the polyp.

Dr. RICE: The treatment of those cases of multiple nasal polypi which form the text of Dr. Casselberry's paper is very difficult. After all tangible growths have been removed by the snare the entire mucous surface in the affected nostril is so thickened, and the middle turbinated bone is frequently so much hypertrophied, that great obstruction still exists. Even after all hypertrophy has been removed the mucopurulent secretions are very abundant and exceedingly troublesome to the patient. It is not possible with the snare to reach the tissue satisfactorily which is above and behind the middle turbinated bone without first removing a portion of the middle turbinated bone. I do not approve of the application of the galvano-cautery to the surface of the middle turbinated bone, where it is very closely related to the septum. Both surfaces are apt to be scorched, very little tissue is removed, and adhesive inflammation may be the result of such burning. The only rational method of treatment is to remove enough of the middle turbinated bone, so that the thickened tissues above and behind it can be reached and removed by proper manipulations.

A word of caution should be suggested as to the removal of the middle turbinated bone. Only so much of it should be taken away as will secure good drainage and allow treatment of the cavity above. I have seen severe forms of atrophic rhinitis following the wholesale removal of the middle turbinated bone and the use of the galvano-cautery above the neighboring structures.

In these cases of nasal polypi the middle turbinated bone seems to have become so much weakened in its attachments that the entire bone may be removed by the snare if too much of it is included within the loop. The treatment of these cases is troublesome at the very best, and requires careful and painstaking work.

Dr. JARVIS: I am myself a great believer in the surgical treatment of these cases; but I also believe, in contradistinction to what Dr. Bosworth states, that it is possible to find chemical agents that will remove these growths. I formerly employed an application, which I was led to try some years ago, through the suggestion of a physician who had found it very effective. While the treatment in most cases is purely surgical, it is not necessary to make the nose a surgical armamentarium. For instance, why should we use first a snare, then scissors, then a saw, and finally the cautery? It seems to me that this might all be done with two instruments—the snare and the searching forceps. Where small polypoid growths appear, I encircle the base and remove part of the bone with it; the searching forceps I use is of about the thickness of a lead-pencil. With this little instrument these bead-like growths are seized and stripped off one after another; there is no hemorrhage of any account after tearing them away. There is one point which I wish to accentuate: where we remove polypi by means of the wire snare, we use a method which is easy and simple as compared with evulsion and the cautery, and one which is free from the danger of producing septic symptoms. Even if the patient has to come back again for another operation in a year or two, it is not much trouble to repeat the procedure.

Dr. J. SOLIS-COHEN: I would ask the last speaker if he knows of any medicament which, applied to a polyp, will cause it to disappear without surgical procedure? If so, he should state what it is.

Dr. JARVIS: There is no secret about it, it was simply the injection of the tincture of the chloride of iron into the nostril. It is not an elegant application and I am not entirely satisfied with it; but in some cases I have found it effective.

Dr. MULHALL: There is nothing new about that, as it is mentioned in the text-books on surgery years ago. With regard to operating upon these cases, I have a rule concerning the removal of a portion, but not the entire, middle turbinated bone. It came to me by experience. The rule is that where the Jarvis snare can catch the end of the middle turbinated bone, it can be and should be removed. I rise principally, however, to speak in opposition to the views expressed with regard to the use of the galvano-cautery. Some years ago I read a paper condemning the use of the galvano-cautery by Lennox Browne, who claimed that it caused erysipelas and other bad results. I concluded that they were not due to the method, but to the rules of operating laid down by that writer. I have used it in many cases—I should say at least four thousand cases—and have never met with such an accident. My rule is that the platinum wire should be white hot before cauterizing the spot, and it should be withdrawn in the same condition. Lennox Browne's rule was to heat the wire only to a cherry-red heat and allow it to cool inside of the nose before withdrawal. This is sure to be followed by inflammation, for which the operation has been blamed, whereas it is the fault of the operator. It is necessary in some cases to remove part of the middle turbinated bone in order to reach a polyp in the hiatus semilunaris. In one case I recommended the removal of the entire middle turbinated bone for a man who had had polypi removed for thirty years; the operation was done with entire success.

Dr. MACKENZIE: I have been very much interested in the discussion, especially in the remarks of Dr. Jarvis, and in the

simplicity of the means to be used in the class of cases under discussion. I can not, however, concur in his statement that everything can be done with the snare. In these bone cases I have found considerable difficulty in getting the snare through the bone; when the bone was thoroughly engaged in the loop, it was with the greatest difficulty that I got it home. Therefore, in many cases, I have been obliged to relinquish the snare in favor of other means. I am also completely in accord with Dr. Mulhall in his estimate of the value of the galvano-cautery; I keep it by my side all the time. I use it every day, and among several thousand cases I have never seen an accident. I use it at a heat just bordering upon a white heat, and just whiter than a cherry-red. I have seen a purulent discharge following the application and lasting several weeks, and some sloughing after removing large pieces of the turbinated bones, but no serious accident. At the same time it must be admitted that unskillful use of the cautery might cause sloughing and do great damage.

Dr. ROE: The main reason for the failure to get good results after the employment of the galvanic cautery, and the cause of the occurrence of inflammatory and septic troubles, is that the burned surface, after the operation, is not rendered thoroughly aseptic. This should be done as thoroughly after a cautery operation as after a cutting operation, and kept so until the parts are healed. When this is done we never have any inflammatory or septic troubles and seldom a purulent discharge. This fact was pointed out by me in an article read last year in Berlin before the International Medical Congress.

Dr. ASCH: My experience is thoroughly in accord with that of Dr. Jarvis. I find that the snare fills every indication; the operation is a slight one and, if necessary, can be repeated at a future time. But few growths require more than one or two operations. With regard to the objection of Dr. Mackenzie, I think that the trouble is due to defective instruments. Where the snare and holder are made of steel, there is no difficulty in cutting through bone—certainly not with an instrument made as mine are. Like Dr. Jarvis, I have never seen the use of the snare followed by septic trouble. I take the precaution always to immerse the wire and snare in a carbolyzed solution before operating.

Dr. JARVIS: The galvano-cautery is harmless, why is it that we read of the case of Ziem, where total blindness followed its use in one eye; or that of Quinlan, where meningitis occurred? I also recall a case where erysipelas resulted, where the operator was sued for malpractice.

Dr. MULHALL: I attribute such accidents to an imperfect method of operating.

Dr. ROE: I should say imperfect antiseptics.

Dr. SAJOUS: I would confirm the statements just made as regards improper use of the galvano-cautery.

Dr. CASSELBERRY: I feel a little guilty for calling out a discussion upon all the methods of treating polypi. My contribution was meant to limit the discussion to a newer field—the removal of the anterior portion of the middle turbinated bone in certain cases. I hardly think that the removal of a small portion of the middle turbinated bone could give rise to atrophic rhinitis. With regard to the transition of hypertrophic into atrophic rhinitis, I would offer the suggestion that it may occur more frequently in the climate of New York, as I have never seen a case in Chicago where hypertrophic change has passed into an atrophic. With regard to the use of chemical agents, especially the tincture of iron, alcohol, etc., I think that where there is general relaxation of the parts such astringents are useful as adjuncts to surgical treatment. Alone they can not often reach the actual seat of disease. With regard to the snare, I may say the same, concerning, however, a much smaller proportion of cases—that one can not always reach the growth with the

snare; and the cauterly also fails at times. Then I resort to the operation described. In conclusion, I will merely refer to the remark that has been made about removal of the normal turbinated body; the turbinated body in these cases is never normal; it is hypertrophied, sometimes covered with polyp-buds, and often curved over toward and crowding upon the septum. Moreover, I never removed the whole body, but merely the antero-inferior end. In the case where meningitis set in, following the use of the galvano-cauterly, it was probably a case of inflammatory ethmoiditis, and the meningitis set in before the cauterization; the use of the cauterly was merely a coincidence, occurring in an effort to relieve symptoms due to the ethmoiditis.

**Various Forms of Disease of the Ethmoid Cells.**—Dr. F. H. BOSWORTH read a paper on this subject. (See vol. liv, page 505.)

Dr. MACKENZIE: I take great pleasure in saying that Dr. Bosworth has at last read a paper with the contents of which I can entirely concur. I wish to say this in opening the discussion on the paper that we have just heard, and to thank him for that paper. I agree with him in his remark about the confusion of cause and effect that has been made by Woakes, whose theory is only explainable on this ground.

Dr. JARVIS: I can confirm the remark made by the reader of the paper concerning the dangers of removing the cap from the turbinated bone and opening the cells, and also of removing the bone, on account of the existence of a myxomatous growth. In such cases the unfortunate patient may perish with meningitis, from extension of the inflammation through the ethmoid cells. After the removal of the posterior end of the middle turbinated bone the nostril may be found to be occluded by a soft myxomatous growth. It is my rule not to stop until all this obstruction is removed. I believe we may have pure ethmoiditis. I recall a case of blood poisoning in which I was called in consultation after pyæmic symptoms had set in. I drilled away the side of the septum into the body of the turbinated bone, and in this way obtained free drainage. It required a number of operations, but the patient made a good recovery. It is of interest to note that in these cases of non-myxomatous ethmoiditis we often have to deal with a condition of malformation in which the septum is deflected to one side so as to completely occlude the upper part of the naris. I recall one case, that of a lady, who had traveled extensively without obtaining relief, in whom the trouble was removed by chiseling away the septum until the channel was clear. I agree entirely with Dr. Bosworth in his views upon the treatment of ethmoiditis.

Dr. WRIGHT: I did not understand whether or not Dr. Bosworth referred to cases of acute ethmoiditis; but since Dr. Jarvis has mentioned such a case I may also refer to one which I saw last spring. My observation is that these patients generally get well after thorough cleansing of the nose; washing it out frequently with a syringe or spray is often sufficient. Such an operation as Dr. Jarvis resorted to would rarely be necessary.

Dr. MULHALL: I subscribe to the views expressed by the reader of the paper and to his remarks upon a class of diseases which we all recognize and which he has grouped in a way that will be of great value. I wish simply to state that I coincide with his statement that in the class of cases referred to we are tempted to radical measures for the relief of the condition when milder ones would answer and are safer. I recall a case coming under my observation in which the middle turbinated bone was removed and the patient died; however, the operation was not done aseptically; it was before the day of the introduction of present measures into surgery. I now use the curette, but always take the precaution to do the operation in a perfectly aseptic manner. The danger of opening the ethmoid

cells and of lighting up inflammation is such as to make such measures indispensable.

Dr. JARVIS: I should like to say in reply to the remark of the last speaker, with reference to securing asepsis, that there is no method that will equal the use of the cold wire. I have never seen septic symptoms produced by the application of the cold wire in operating. I have seen such symptoms after the use of drills, but I think as long as the cold wire is used we can proceed with impunity. I do not think that any gentleman present can report a single case in which septicæmia followed an operation with the cold wire snare.

Dr. BOSWORTH: I have nothing to say in closing the debate, but I should not let the occasion pass without acknowledging the remarks of Dr. Mackenzie and my gratification at having him agree with my conclusions. With regard to the theory of necrosing ethmoiditis of Woakes as the cause of all cases of nasal polypus, I think he still stands almost alone in his views.

**The Symptoms and Pathological Changes in the Upper Air Passages in Influenza.**—Dr. J. SOLIS-COEN read a paper in opening a discussion on this subject. (See page 344.)

Dr. SURELY: I am very much interested in the paper, especially because of having met so many cases of tuberculosis the origin of which was apparently in an attack of influenza. Another point to which I would like to call attention is one noticed by some French writer, in an article published some eight or ten months ago, in which the idea was advanced that the late pandemic of influenza was a modification of, or allied to, cerebro-spinal meningitis. There is certainly a resemblance clinically, because in our district there were neurotic symptoms manifested in a majority of the cases strongly resembling the latter disease. A third point that I would mention is that the paper formulates the belief that it is a chemical metamorphosis which takes place in the various cells and tissues which constitute the original features of the disease. In our chemical work, incident to the examination of tubercular matter, etc., we have been unable yet to separate a distinct ptomaine or toxine from them. However, fluids treated with phosphotungstic and phosphomolybdic acids yield deposits which, when injected into the tissues of guinea-pigs, gave rise to intense glandular irritation and inflammation, which, in some cases, reaches its height in three days, afterward gradually subsiding. In one of the animals, where suppuration took place, examination of the pus showed no bacteria whatever, but pus cells and broken-down lymph material only. If we had allowed the animal to live, it is possible that the characteristic lymph elements might have been developed. The observations of the author of the paper can be borne out by the results of such experiments. The why and wherefore, of course, I do not know, but we shall pursue these experiments further upon the larger animals, such as calves or goats. I think that the chemical poisons of tuberculosis may be considered as related to that or those of pandemic influenza, whatever it is.

Dr. WRIGHT: I was much struck during the second epidemic of influenza by the disproportion between the amount of actual disorder which could be found upon examination and the amount of suffering and constitutional disturbance. I saw a large number of throat and nose patients in the hospital, and could find only a slight pharyngitis or rhinitis; and the way we usually made the diagnosis of influenza was by observing the slight lesions of the nose or throat and the large amount of constitutional disturbance.

Dr. ASER: I think that it would be well for the representatives from the different sections of the country to give their experience as to the manifestations of influenza, so that we could ascertain whether the upper air passages were equally affected in the different localities where it prevailed. In my own expe-

rience in New York there was not a marked increase in the number of such cases applying for treatment nor in their gravity, nor did I remark in the cases of influenza which came under my notice a uniformity of lesion. There was, however, one lesion which was frequently, though not always, present—viz.: an inflammation of the tonsils, attended by an extreme depression, which I have noticed under no other circumstances. Though follicular amygdalitis is usually marked by depression, I have never seen it so severe as in these cases. It was so great that in some cases it gave me reason to fear for the safety of my patients.

Dr. CASSELBERRY: The point raised by Dr. Asch is a very valuable one, and in fact I brought it out yesterday in connection with disease of the mucous membrane of the nose. As regards the climates of New York and Chicago, there seems to be a decided difference in the number of cases of transition from the hypertrophic to the atrophic stage of chronic rhinitis, which transition is rarely seen in Chicago. With regard to the point raised by Dr. Wright concerning the severity of local manifestations of influenza in the upper respiratory tract in Chicago, we observed them often of a violent type, commencing with severe rhinitis and naso-pharyngitis, and extending into intense degrees of laryngitis, bronchitis, and even pleuritis. In the nose I have not always at first been able to distinguish between the local manifestations of influenza and those of ordinary severe inflammatory attacks; perhaps in the former the mucous membrane had a more bluish aspect, and this appearance I had not attributed to a specific venous congestion, but to the violence of the attack.

Dr. WRIGHT: I might supplement my remarks by the statement that with us in New York we observed a much larger proportion of cases of suppuration of the middle ear than among ordinary cases of throat inflammation.

Dr. S. SOLIS-COHEN: The comparative frequency of special lesions of influenza in the personal experience of any physician will depend largely upon the character of his practice. For instance, in my general wards in the Philadelphia Hospital characteristic manifestations of the disease in the upper air passages were comparatively few; and, in fact, I can recall but two cases, both presenting the "solid œdema" referred to by the reader of the paper. On the other hand, I saw a much larger percentage in my private and consultation practice. I would express my admiration of the graphic expression "solid œdema," used by Dr. Glasgow in his original paper. The character of the manifestation has been fully described and I need not repeat it. The first case of influenza I saw in 1889 was one in which this solid œdema affected the tonsils and soft palate. Through the knowledge gained from the paper of Dr. Glasgow, I was enabled to make the diagnosis, which otherwise I might not have been able to do, as it was some months before general recognition of the existence of the pandemic. I have now under care a convalescing case which at first I was inclined to diagnose as one of typhoid fever; but its further progress has led me to think it rather a case of the peculiar pneumonia described by Dr. Glasgow, and I mention it now only to suggest the wisdom of greater attention to this peculiar condition. The favorable effect of influenza upon tubercular processes is, of course, exceptional. Hundreds of cases of tuberculosis have been hurried to the grave by the epidemic.

Dr. S. SOLIS-COHEN: I would supplement my remarks with the statement that with us, in Philadelphia, otitis media was also very common. In some cases other symptoms were lacking, and only from the prevalence of influenza and the occurrence of several cases among the children in a family was I enabled to recognize its infectious character. In many instances it was bilateral, one ear becoming affected as the other healed.

Dr. JARVIS: The paper read by Dr. Cohen presents clinical features of great interest which we may very well study. I refer especially to the encephalopathy of malignant disease and tuberculosis. Only a few days ago a most distinguished dermatologist expressed a belief that he had seldom seen cases of lupus in which erysipelas had occurred where a favorable influence was not exerted upon the course of the disease.

Dr. ROBINSON: I wish to simply say one thing, perhaps not bearing directly upon what Dr. Cohen has said. In connection with influenza, I have been witness to disturbances of the middle ear which seemed to me to be very interesting for several reasons. I could not say precisely in what the inflammatory condition consisted. There did not really seem to be any notable disturbance of the Eustachian tube, or inflammation of the canal; but these patients suffered a very great deal. There was dullness of hearing, noises, worse in one ear than in the other, and a sensation of a foreign body in the ear; but I could not determine anything of a pathological nature simply by sight. The obstinacy of these cases was something extremely remarkable. I saw a lady only a few days ago who has been troubled in this way for at least twelve months, in spite of general and local treatment. I wish merely to add this to the discussion—that there is something peculiar hitherto unclassified in the auditory disturbances following influenza.

Dr. JARVIS: According to my observation, the victims of this class of affections of the upper air passages were those having more or less pathological deviation of the septum; in other words, those who were suffering with chronic rhinitis. I would ask if this is borne out by the experience of any other gentleman present?

Dr. ROE: I observed, when the epidemic first appeared, that those who had chronic ear, nose, or throat disorders were those who suffered most from the influenza. I also noticed in this connection that the apparent cause of this œdema, which was first described by Dr. Glasgow and now mentioned by Dr. Cohen in his paper, was due to a vaso-motor paresis associated with cardiac weakness. In nearly all cases I have been led to look upon this passive œdema as not associated with any inflammatory trouble, but as one due to lack of sufficient circulation, resulting from weakness of the heart. In the treatment of these affections I have obtained the best results from the administration of cardiac stimulants in addition to other medication that may be indicated.

Dr. SHURLY: We have three distinct grades of severity among the cases of the late pandemic of influenza, and I wish to exclude entirely instances of ordinary influenza that we usually have in our northern climate every winter. In some cases the general affection is light and, perhaps, only lasts twenty-four hours, but the upper air passages seem particularly affected. Just as in epidemics of scarlet fever and measles, there are certain persons who have nasal catarrh or rhinitis, but who do not manifest the symptoms of scarlet fever or measles. Now I take issue with those gentlemen who hold that a deflection of the septum, or any purely local condition of the air passages, induces the attack; or that the nervous, pandemic, general disease is influenced by any local condition.

Dr. JARVIS: I wish to explain that I do not maintain that the pathological process is confined to the nostril, but that it constitutes the starting-point from which the disease may extend to the throat and lower air passages, producing more serious symptoms. I did not mean that the disease was due to a deflected septum, but that this condition might be a predisposing cause.

Dr. S. SOLIS-COHEN: The majority of the cases of influenza which I have seen had no chronic nasal trouble.

Dr. SAJORS: I think that the matter is easily explainable.

The gentlemen are looking at the matter from different standpoints, basing their conclusions upon their individual observations. Where there is already local disease, the patient will find that there is more local disturbance during the progress of the disease.

Dr. ROE: I did not mean to say that the local diseases that I referred to were the cause of the general symptoms, but that when these local disorders exist in the upper air passages the person is predisposed to attacks of influenza. I do not, however, regard the influenza as merely a local trouble, limited to the upper air passages, but believe it to be more severe when the air passages are diseased.

Dr. GLASGOW: The complications, or rather the pathological changes, occurring in the upper air passages as the result of influenza have been fully described, and I can add very little to what has been said. There are a few points, however, which have not been mentioned which have attracted my attention. During the epidemic I have met with a greater number of cases of acute suppuration of the antrum than I have seen at any other time. I think it was also true that during the prevalence of the disease the tendency of all inflammations of the closed cavities was to become purulent. If pleurisy occurred, it was empyema; pericardial effusion was purulent. In fact, according to my experience, purulent inflammation was a characteristic feature of the disease. My experience is fully in accord with the writer of the paper in stating that during the prevalence of the epidemic there was an almost complete disappearance of catarrhal inflammations of the upper air passages. The reappearance of this condition was an evidence that the epidemic was disappearing. I have not observed that local disease in the nasal passages had any causative effect in provoking the disease. Where pathological changes have produced obstruction, the addition of the cellular infiltration of the mucous membrane has certainly added to the distress. There is one point in Dr. Cohen's paper which has gratified me, for it was upon this point that I was criticised when I read my paper before this society on Oedematous Disease of the Upper Air Passages. I refer to the presence of an exudation in the throat bearing a certain resemblance to the diphtheritic membrane. I can heartily agree with Dr. Cohen in believing that influenza is essentially a disease of the blood. I have always considered it analogous to typhus or erysipelas—a general infectious disease. In regard to the connection of influenza with tuberculosis I have positive views, which are based upon extended clinical experience. According to my observations, I should say that influenza rather encourages the production of tuberculosis, instead of being a protection against it. The interstitial cellular infiltration of the alveolar walls—the pathological condition in influenza—seems to be a most fertile soil for the development and growth of the tubercular bacillus. Microscopic examination of the sputa of cases which have become tubercular shows enormous numbers of bacilli, and resembles rather a culture of the laboratory than human sputa.

The weakness of the heart has been referred to by the speaker, and I can fully indorse all that he has said. Cardiac weakness is a constant accompaniment of the disease; it is due to a change and weakening of the heart fibers, similar to that existing in infectious diseases.

Dr. J. SOLIS-COHEN: The supposed connection between cerebro-spinal meningitis and influenza, which has been referred to in the discussion, was first brought to the attention of the profession by Dr. Levick, who was then physician to the Pennsylvania Hospital, I believe about 1864. I did not wish to be understood as saying that influenza will cure tuberculosis. I have seen too many fatal cases of tuberculosis hurried off by influenza. I thought it peculiarly interesting that I had seen one

case of tuberculosis of the larynx and one of malignant disease of the pharynx cured by the attack of influenza.

**Useful Deductions derived from the Study of a Case of Cicatricial Contraction of the Larynx, possessing Unusual Clinical Features, with Exhibition of Specimen.**—Dr. W. C. JARVIS read a paper with this title. (See vol. liv, page 509.)

Dr. J. SOLIS-COHEN: Mr. President, I have looked at this specimen very carefully, and I can not divest myself of the opinion that if you were to cut through this stricture in the upper part of the larynx, you would find a normal glottis beneath.

Dr. MACKENZIE: The paper reminds me of a case which I had several months ago at the Johns Hopkins Hospital. The patient had syphilis, and suffered very much with dyspnoea. He had been treated for eighteen months for asthma. Upon examining his larynx, I found bilateral abductor paralysis. His dyspnoea was so great that I feared his death in my office, and I got his father to take him to the hospital in a carriage, with a note to the hospital resident to perform tracheotomy at once, if another attack came on, without waiting for my arrival. The operation was done at once by the house surgeon, but the expected relief did not appear. In fact, the dyspnoea not only got worse, but expiratory dyspnoea was added to the inspiratory difficulty. This showed, to my mind, that there must be some obstruction below the seat of operation which had been overlooked. The patient sank, and in the course of a few days died. I thought that it might be due to stricture of or pressure upon the trachea. The post-mortem was made by Dr. Welch, very carefully. No trace of syphilis was found in any part of the body, except in the respiratory organs. In the apex of one lung was found a large gumma. Both recurrent nerves were compressed, and were found in a mass of half cicatricial tissue and half enlarged glands. There was pressure upon the nerves, and the trachea at its bifurcation was so narrowed by the tumor and by contraction following ulceration, that it was with the greatest difficulty that a very fine probe could be forced through the stricture. There were other ulcers in a state of cicatrization in the neighborhood. The complete examination has not yet been made, but I may state that in the nerves we found certain fibers of both recurrent laryngeal nerves in a state of fatty degeneration. This case was extremely interesting to me because of the combination of the stenosis with the degeneration of the nerves and the external pressure of a tumor. This was all subsequent to the gummatous deposit in the lungs. It is very seldom that we find this location of syphilis strictly in the respiratory organs, without being manifested in any other part of the body; it is a paradoxical expression of the syphilitic infection. The patient was in the process of cure; but the cicatricial contraction of the ulcers made pressure upon the trachea and upon the nerves and caused his death. Of course there was also a condition of hypostatic pneumonia found at the examination after death.

Dr. ASCU: In a case like that reported by Dr. Jarvis I think it advisable to try dilatation; I have reported some cases which were cured and some much improved by this treatment. Of course the amount of dyspnoea might necessitate tracheotomy; but the dilatation could be practiced after the operation.

Dr. CASSELBERRY: I am greatly interested in Dr. Jarvis's case, and wish to speak of the danger of undertaking palliative treatment in cases of this kind. I recall one case of my own which in many respects is similar to the one before us. It was a man of middle age, suffering from syphilitic contraction in the upper part of the larynx, with attacks of dyspnoea, which were sometimes of dangerous severity. Tracheotomy was recommended and refused. It was just five days afterward that he suffered a severe attack of dyspnoea and perished before aid could

reach him. Now, I maintain that a man going about with such a condition of the larynx, exposed to all sorts of influences which might bring on an attack—such as cold or inhalation of dust or other irritants—is every moment in much more danger of his life than he would be from the performance of tracheotomy. I claim that palliative treatment with O'Dwyer's tubes in such severe cases is dangerous. We should perform tracheotomy first and then palliation if you choose; but first of all put the patient in a safe condition as regards his life, and treat the stricture afterward.

Dr. S. SOLIS-COHEN: This specimen very much resembles the laryngoscopic image of a case in the practice of my brother. Upon cutting through the contracted portion of the larynx—a therapeutic operation undertaken during life—there was found a healthy glottis beneath. Perhaps he recalls the case.

Dr. J. SOLIS-COHEN: Yes, I remember the case you refer to.

Dr. WRIGHT: I am interested in the specimen, but less on account of its extraordinary character than its ordinary character. There are a large number of cases of syphilitic contraction of the larynx presenting themselves having the same features. I have a case now under observation in which the inflammation, commencing in the nose, extended down the throat and into the larynx with cicatricial formation; and it was much benefited by iodide of potassium. I saw several cases of tracheal syphilis last winter which lend emphasis to Dr. Casselberry's remarks. Take a case of this kind; if he were to have an attack of ordinary laryngitis he would drop dead in the street; the slightest swelling could not help but cause suffocation. The patient would die suddenly. Certainly, in these cases it is our first duty to explain the condition clearly to the patient; he may refuse an operation, but it should be explained to him so that he may understand the danger he is in without it. I am glad that Dr. Jarvis has brought this subject before us for discussion.

Dr. SAJOUS: Speaking of the dangers to be encountered in these cases, I should like to include iodide of potassium in the list. The fact that œdema sometimes follows its use should be borne in mind in treating these patients.

Dr. WRIGHT: In cases of extreme stenosis I want to say that the administration of iodide of potassium may have the result just referred to, and if it is given, I would say, get out your tracheotomy instruments and be ready for immediate operation. I always treat these cases in a hospital, where I can keep them under observation.

Dr. SAJOUS: I would also state that in syphilitic laryngitis I noticed a connection between the administration of the iodide and the appearance of the œdema; as soon as I gave the iodide the œdema would appear, and would disappear as soon as it was stopped.

Dr. S. SOLIS-COHEN: I am glad that Dr. Sajous has brought this matter up. Few physicians keep in mind the possibility of producing œdema when they give large doses of iodide of potassium in syphilitic affections of the throat. It is not a mere theoretic danger. Professor S. W. Gross used to relate to his classes a case in which he had to sit up all night, prepared for instant tracheotomy. This danger is present in every case in which large doses are given at the first, without previous gradual increase, even where there is no local disease of the larynx. As to the specimen presented by Dr. Jarvis, any physician or surgeon who counsels against tracheotomy in such a case is taking a very grave responsibility.

Dr. J. SOLIS-COHEN: With regard to the occurrence of œdema in these cases, I must say that I can hardly see where the œdema is to come from on account of the dense infiltration of the parts; but there are other dangers than those from iodide of potassium. In several cases occurring in the practice of some of the most prominent men in the profession, in which I have urged

the performance of tracheotomy which was not done, the patients afterward died. Another point is that in cases of decided stenosis there would be danger from an attack of bronchitis, since a small pellet of mucus might cause strangulation. I was surprised that any one should use O'Dwyer's tubes when I first saw them, their caliber was so small; I did not see how they could possibly benefit the patient. I always make it a rule to use as large tracheotomy tubes as possible. I afterward found that patients could breathe very well through the small tubes of O'Dwyer.

Dr. JARVIS: In reference to Dr. Cohen's remark that there is a healthy larynx inferiorly, I should state that I meant to convey the idea that the contraction was limited to the upper part of the larynx. I of course knew that the cords were not involved; this was recognized during life. I was very glad to hear the remarks made about iodide of potassium. It is a valuable remedy in these cases, but it is not necessary to give it in overwhelming doses; small doses would be safer and sufficient to afford relief. I was also pleased with the remarks made about intubation. I am sure that if any gentleman present had seen the case he would have agreed with me as to the impracticability of the O'Dwyer tubes in this case; and I think that he would have been very glad to get off without causing serious inspiratory spasm during the examination. With regard to Dr. Casselberry's remarks, I stated that tracheotomy was indicated and that I had urged the patient to submit to the operation, but he thought that as long as he was relieved by the inhalations he would not have it done. I did not feel like sending him away just because he would not do exactly as I desired. I am glad that this report of the case has been so well received and that the discussion shows that the members agree as to the propriety of the measures suggested by me for the patient's relief.

**The Relation of Disturbances of the Mucous Membrane of the Upper Air Passages to Constitutional Conditions.**—The discussion of this subject was opened with a paper by Dr. BEVERLEY ROBINSON. (See page 340.)

Dr. MACKENZIE: The only thing that I have to complain of in the paper of Dr. Robinson is the unnecessary stress which he lays upon serofulous inflammations of the larynx or upper air tract. I suspect that the essayist is still under the influence of the old French school, and it is owing to his early training in that school that he comes to lay such stress upon serofulous inflammation in contradistinction to syphilitic and tubercular ulcers. I have read much of the literature of this subject and have come to the conclusion that there is very little difference between serofula and syphilis on one hand, and serofula and tuberculosis on the other. I think that there is no ground for belief in an ulcerative serofulous inflammation of the throat.

Dr. JARVIS: I should hesitate to accept the radical view of Dr. Mackenzie that serofulous inflammation is always tuberculous. We can not always demonstrate by microscopic examination the presence of bacilli. Many serofulous disorders come more correctly under the head of constitutional syphilis.

Dr. WRIGHT: I should like to know what serofula of the upper air passages is if it is not tuberculosis and if it is not syphilis. What is it?

Dr. JARVIS: I do not absolutely accept the term serofula. This condition might be due to inherited syphilis. I do not believe in making the comprehensive term "tuberculosis" cover all these cases. I might mention a case of necrosis coming under my observation in which the attending circumstances, clinical history, and social surroundings make it difficult to entertain the view of inoculation with syphilis, and there was no evidence of tuberculosis. In this patient the manner and result of treatment were such that we could not entertain the view that it was a case of tuberculosis or syphilis.

Dr. MULHALL: What has scrofula to do with syphilis? I remember the remark of a man with whom I had the pleasure of being associated for three years—I refer to Mr. Hutchinson, of London, who knows something of syphilis. The statement was that syphilis is not transmitted to the third generation. I offer an explanation of what we vaguely call "scrofula." I published a paper some seven years ago upon atrophic rhinitis, in which I gave a definition of scrofula as a peculiarity in the constitution or age of the parents by which one or both of them are unfitted for transmitting healthy offspring. For instance, the child of drunken parents may be scrofulous; the child of senile parents may be scrofulous; the child of syphilitic parents, if conceived in the stage of cachectic depression, may be scrofulous; the child of phthisical parents may be scrofulous. Therefore, scrofula affects the product of conception of parents who are in a profoundly depressed state of nutrition, whatever it may be due to.

Dr. S. SOLIS-COHEN: I have been very glad to hear this subject brought forward for discussion, since, unless we recognize an abnormal constitutional condition, which we may call scrofula, we will not treat its subjects properly, either for local disease in the upper air passages or for local or general disease elsewhere. Dr. Mackenzie believes that Dr. Robinson is at fault in paying deference to the opinions of the older French writers. I for one would like to express my indebtedness to those French writers, and especially to Lugol. Even with all our new lights, if we turn to the writings of that great man we can certainly learn something about scrofula—a disease which the elder Gross called the child of syphilis and the parent of tuberculosis. But syphilis is not the only cause of congenital scrofula. As Lugol pointed out and as Dr. Mulhall has just said, it is the inheritance of a child whose parents are, from whatever cause, physically incompetent to produce normal offspring, and it forms a species of what we vaguely call "diatheses." We have no better way of characterizing this condition, especially from the standpoint of the modern cell doctrine, than by stating the position thus: All manifestations of life enter this world as living cells; every cell springs from a parent cell. If that parent is intrinsically deficient or by extrinsic causes rendered unable to transmit to the offspring the necessary vitality or life force, the product will be incomplete or scrofulous. The scrofulous state may likewise be acquired by depression, privation, or excess. Benjamin Ward Richardson says that the secret of long life consists not so much in any peculiar endowment of the body as in the nice adjustment of parts. Going a little farther than this, we see throughout Nature a constant balancing of opposing forces. It is exemplified alike in the revolutions of the planets, in the course of the winds, in the swing of the pendulum. As in the macrocosm, so is it in the microcosm; the heart of man throbs as the heart of the universe. In the scrofulous child there is not that nice balance of opposing forces. Either there is not enough innate constructive force to repair the tissues broken down in the exercise of function, or there is a failure from incomplete development or, in the acquired condition, from incomplete nutrition, to supply energy to meet the destructive forces of the environment. This state has been well described by a modern French writer (Jaccoud), as one of "hypertrophy" or "congenital dystrophy"; but names are less important than the fact that the organism is unfitted to survive in the struggle for life. The child under such circumstances is not necessarily born tuberculous, but may become tuberculous. Local expression of the disease in the upper air passages or elsewhere is determined by some trauma or other accidental excitant. The local expression may not differ to sight from the local expression of other causes, but its course, its rebelliousness, the general condition of the patient, help the diagnosis.

I may refer to a case of scrofulous ozæna, which was neither syphilitic nor tuberculous, that I saw ten years ago in a boy whose brother and sister have since developed tuberculosis. My patient himself has not yet developed tuberculosis, though he may do so. At all events, the general history of the patient, rather than the shape of the ulcerations or the quantity of bone that necrosed, shows that his was a case of scrofula and not of tuberculosis, which his brother and sister manifested. The parents are neither tuberculous nor syphilitic, but they were, when the children were born, overworked and ill-nourished because of their poverty. I heartily agree with Dr. Robinson that in treatment, as in diagnosis, we must look upon the fundamental constitutional condition as more important than the local accident that comes under our eyes.

Dr. GLASGOW: I am a firm believer in the constitutional origin of many of the pathological conditions of the upper air passages—not from a theoretical, but from a clinical standpoint. That this view is not accepted more generally seems to be due to the fact that physicians are looking too closely to the local processes. I came many years ago to the conclusion that many of the cases showing congestion of the upper air tract could be promptly relieved by proper attention to constitutional rather than local conditions.

I am thoroughly pleased to hear the term scrofula again. I know I am out of date, but to me it is one of the most expressive terms in the medical vocabulary. The influence of my early training, listening to the teachings of Scoda and Oppolzer, made such an impression that it has been difficult for me to accept the views of later German pathology. I do not see that any addition can be made to the definition of scrofula as given by Dr. Mulhall and Dr. Cohen. Clinically the term designates a certain condition of the mucous membrane when it is applied to the air passages. In persons of the strumous diathesis inflammatory processes are prone to take on a subacute or chronic character. There is great infiltration of tissue with a lessened tendency to a return to the normal condition. The modern school would embrace all the conditions formerly known as strumous or scrofulous under the general name of tubercular infiltration. To me this seems unfortunate, when we look at the condition from a clinical standpoint, for we see many cases where we can certainly make a favorable prognosis. The name strumous would indicate this, while tubercle is a word of ill-omen. The confusion which is caused by the use of the word tubercular to indicate a variety of conditions is not justified by the fact that we often find the tubercular bacillus in this tissue. The old doctrine of Niemeyer—that "the great danger to the strumous lies in the possibility of becoming tuberculous"—is strictly in analogy with our experience at the present time, when we consider the infectious pneumonia of influenza. No one would consider this pneumonic condition as tubercular, but we do know that the pathological condition of the lung in this disease proves a most fertile soil for the growth of the tubercular bacillus, and large numbers die with an acquired tuberculosis. The bacillus grows and develops in the laboratory in several culture mediums, and is it not equally true that in the human body there exist several pathological conditions which furnish a suitable and fruitful soil?

Dr. BOSWORTH: In estimating the constitutional or other origin of any local disease of the upper air passages, it is necessary to differentiate between diseases of the nose and those of the naso-pharynx. I do not think that the constitutional state has much to do with catarrhal inflammations of the pituitary membrane, in a great majority of cases at least. But when you come to the naso-pharynx you will find catarrhal conditions very frequently dependent upon constitutional diseases. Disease of this region is most likely to occur between the age of

eighteen and forty years. I have found that most catarrhal affections locate themselves at this point in the naso-pharynx between these ages, thus establishing conditions which are aggravated by disorders in other parts of the body. This leads to the question, What has the lymphatic system to do with these disorders? and, still further, to the discussion and definition of struma. We think that we know about all there is to know about the nose and its disorders; but we have in the lymphatic glands existing in the naso-pharynx a subject for study—one that we know comparatively little about. Catarrhal diseases located in the naso-pharynx, secondary or primary, are dependent upon disorders of the lymphatic system; the source of the lymphatic disturbance is in the underlying constitutional condition. I do not like the term scrofulosis: I prefer to call it struma. I think, if we investigate the cause of the lymphatic condition that I have mentioned, it will lead us a step farther toward comprehending what is described as struma. My main point, however, is that the constitutional state has very little to do with diseases of the nose, but has very much to do with diseases of the naso-pharynx.

Dr. INGALS: I am particularly pleased with Dr. Robinson's paper, as it directs us to a rational treatment of a comparatively large class of obscure cases whose real nature is liable to be overlooked. I can not understand why constitutional conditions should not affect the nose as well as the naso-pharynx, and I can not agree with the last speaker that the nose is never affected in cases considered scrofulous.

Dr. WRIGHT: In answer to my question of what is meant by scrofula of the upper air passages, I have been informed that constitutional scrofula is, but have not been told how to recognize a scrofulous lesion in this location.

Dr. MULHALL: Six months ago I wrote a paper on The Effects of Diet and Exercise upon the Cure of Simple, Uncomplicated Chronic Inflammation in the Human Body. I think I proved in that paper by several new facts that constitutional conditions do affect the nose. I furthermore proved that to the dyspeptic disorders of Americans and their careless manner of eating and lack of physical exercise must be ascribed the cause of our national disease—catarrh—and not to our climate or any meteorological conditions whatever. I think that I also proved that patients, by proper hygienic treatment, by careful attention to diet, exercise, and clothing, can be cured without local treatment. I referred, as examples, to the cases of

two pugilists who had catarrh, whose noses were stuffed and hyperæmic, while they were spending their time in saloons and eating and drinking too much; they were in a state of hypernutrition. They used various remedies for the catarrh, both with and without the advice of physicians, without benefit. They then went into training for a prize-ring encounter, and two weeks before training ceased the nasal troubles entirely disappeared. I also referred to other cases in which equally good results were had from improvement of the personal habits of patients with nasal catarrh. Without this hygienic help, I denounce local medicinal treatment as utterly useless, except from a financial standpoint.

Dr. ROBINSON: With all respect to Dr. Mackenzie, who credits me with not forgetting my early training, I would state that I am not unfamiliar with recent French literature and German literature also. We are not yet in a position to place an exact value upon Koch's tuberculin in diagnosis. It is not possible to decide in every case whether a lesion is a tuberculous manifestation, or simply a case of so-called struma or scrofula affecting this locality and the tuberculous deposit still remaining doubtful. All of us are aware that there are cases of this kind in which the microscope fails to prove the lesion tubercu-

lar. What, then, shall we call them if they appear in patients evidently scrofulous? I am glad that the president has also expressed his approval of the views which Dr. Cohen so very eloquently set forth in his exposition of scrofula. We must not lose sight of the general ground of medicine, otherwise we will lose ourselves in minutie.

I submit that, in the presence of a scrofulous manifestation in the upper air passages, we are forced to call it something, and, if we can not pronounce it tubercular, what can we call it? We will have to fall back upon scrofula for the want of a better name—just as, in speaking of "catarrh," as Dr. Bosworth has admitted so forcibly, in some cases we are obliged to fall back upon general ideas and provisional names, perhaps without expressing ourselves positively as to the case being necessarily of one kind or another. For further consideration I will refer those interested to Dr. Keyes's last edition for the diagnosis between scrofulosis, tubercu'osis, and syphilis of the throat, where a part of what I have said will be found.

## New Inventions, etc.

### SOME NEW AND IMPROVED INSTRUMENTS.

BY SOUTHGATE LEIGH, M. D.,  
NORFOLK, VA.,

LATE HOUSE SURGEON, MT. SINAI HOSPITAL, N. Y.

DURING a househip of thirteen months on probably the heaviest surgical service in the United States I found many of the instruments in constant use unhandy or complicated. I attempted from time to time to improve and simplify them. I take the liberty of here presenting a few of them. They represent but little originality, yet I hope they may prove to be useful to the profession.

Messrs. George Tiemann & Co. are the manufacturers.

1. *Sponge Holder* (Fig. 1).—In abdominal surgery the sponge holders ordinarily used are unsatisfactory and unsafe, in that the sponges are liable to come off and be lost. Some operators use ovarian clamp forceps, but these are inconvenient from the size of their handles. The

FIG. 1.

holder here presented is intended to overcome both objections. It consists of two long rods with serrated grasping surfaces and an aseptic lock. When closed it holds the sponge *firmly* and securely, and forms a slender *single rod*.

2. *Ether Inhaler* (Fig. 2).—The Ormsbee inhaler has been clearly proved to be far superior to the ordinary inhalers. Its chief advantages are that it consumes less ether and that the vapor is warmed by the expired air. It is, however, somewhat complicated and an expensive

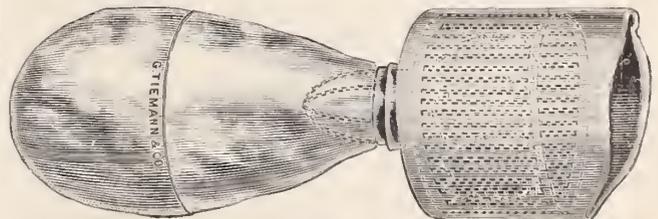

FIG. 2.

instrument. The inhaler here figured is extremely simple. It consists of an ordinary Allis inhaler with a bag attached and with a packing of sponges instead of cloth. It has all the advantages of the Ormsbee, with the addition of simplicity, smaller cost, and a better-fitting mouth-

piece. It can be used as an Allis inhaler by detaching the bag, and has the advantage of simpler packing, which may be easily removed and cleaned.

3. *Needle Holder* (Fig. 3).—This instrument is all metal and easily taken apart. Its action is simple, convenient, and best adapted for rapid work. The sliding catch is so nicely graduated that the operator can exert slight or great pressure on the needle, as occasion may re-

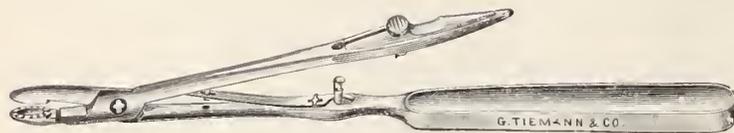

FIG. 3.

quire. While in use its spring prevents the instrument from opening more than a moderate distance. The grasping surface is hollowed for curved needles, and has a groove for Hagedorn needles.

FIG. 4.

4. *Artery Forceps*.—Figs. 4 and 5 represent the forceps in use at Mt. Sinai Hospital, both plain and bull-dog. They have been perfected from time to time, and are now probably the most reliable and con-

FIG. 5.

venient forceps that are made, especially for rapid operating. They have the same useful thumb-slide as the needle holder. They are easily cleaned.

5. *Miscellaneous*.—(a) The sliding catch was found to be so convenient that I have adapted it to the fixation forceps for the eye and to other catch forceps.

(b) The forceps ordinarily used for everting the lids in "grattage for trachoma" frequently cuts the edge of the cartilage. I have had one made with a modification which overcomes this objection.

(c) Bandage cutter: This consists of a large, wide, thin-bladed knife and a miter-box. The bandage is rolled wide and then cut into two or more bandages, according to the width required. It is a labor-saving machine.

## Miscellany.

**The Mechanism of the Mammalian Limb.**—The *Boston Medical and Surgical Journal* for March 17th contains the following lecture by Professor Harrison Allen, delivered before the Academy of Natural Science of Philadelphia:

In all animals the limbs are adapted for locomotion in one of three ways, and each of these is in fixed relation to the plane of support—the first, by which movement is made through air; the second, by which it is made through water; and the third, by which it is made on the ground. Observe, we speak of motion in air, in water, and on the ground. Flying and swimming mammals are surrounded by the medium through which they move, whereas in terrestrial mammals the limb is *on* the ground. The few exceptions that can be made to this statement will not interfere with its truth in general. Again, the size of the limb (notably the foot) in its proportion to that of the body decreases as we pass from the flying to the walking animal.\* Thus the wing of

\* It is curious that we have one phrase to express motion through the water, which is the act of swimming; one phrase to express motion

the bat in proportion to that of the body is immensely larger than are the paddles and flukes of a whale or seal, and both of these, again, are larger than the foot of any of the terrestrial animals. In a word, the size of the limb disposed for progression is in direct ratio to the density of the medium through or on which the animal moves.

Let us examine the skeleton of the dog with reference to the relation which the limbs have to each other, and to the influence which is exerted upon them by the weight of the head and spine. We notice, in the first place, that the anterior extremity is supported entirely by muscle; for we do not acknowledge that limbs with clavicles are better adapted for support than are those without these bones, since when the extremity is fixed at a small movable point to the breast bone it gives little or no assistance to the terrestrial movement. Indeed, the clavicle does not appear until

the limb is adapted for kinds of motion with which terrestrial planes of support have nothing to do. Now, in order that the anterior limb be firmly supported, its motions precisely defined, its strength as well as its mobility rigidly preserved, these muscles must be of enormous size and power. We find that the lines of origin of this muscle-mass are secured from a large region—namely, the back of the skull, the side of the chest, the sternum, the vertebral aponeurosis, and even, in some forms, the hip bones. All the muscles which thus arise are in the forms of sheets, either simple or folded once, twice, or three times. Often from a sheet we may have ribbons evolved, or from a second sheet bandage-like layers, but never thong-like or cable-like bands. These sheets are wonderfully rich in nerves, and extend to, and partially imbed, the shoulder blade so that no part save that which lies directly at the shoulder joint is free. They extend down along the arm at varying distances, always reaching as far as the humerus, and not infrequently the wrist.

How different is everything in the hind limb! The hip bone is fixed to the line of the spine; and the limb, not being supported by muscle-masses, has in every part an entirely different aspect from that of the front limb, and the muscles which do arise from the line of the spine are confined to a surface scarcely any larger than that of the hip bone, and act, of course, not on the part which is homologous to the scapula, but on the lower limb segments. They show slight disposition to extend forward—for example, as in the *psaos*—and scarcely any to extend backward along the caudal vertebrae, yet they preserve the same tendency, as do the fleshy masses of the anterior extremity, to send bundles down—that is, distally—to reach in most forms to points as far as the knee or even the ankle. Since the nerves are more numerous in the sheet than the spindle forms of muscles, it follows that the nerves going to the posterior extremity are relatively fewer than those going to the anterior.

Let us retrace our steps a moment to consider the two limbs from an entirely different point of view than the one above accepted. Assuming that vertebrate life found its first expression in aquatic animals, and remembering that the most important feature in the life of aquatic animals is the means by which the mechanism of respiration is adapted to the medium of water, it follows that problems of the mechanism of the limb in aquatic creatures will be essentially different from air-breathing forms, inasmuch as they all possess respiratory organs, which are fixed to the sides of the neck, or at least to the region back of the head, since in some types, as the fishes, there is no true neck. It will be at once seen, accepting as correct that an anterior extremity demands for high degrees of efficiency an extended surface for the origin of its muscles, that much of such surface is lost in gill-bearing vertebrates, and it is probably true that this accounts for the fact that no such forms possess large anterior extremities. Take, for example, the proteus type of water-newt, which is the best expression known of this phase of development. We have here the gill-arches in front of the small anterior limb, and the chief motion is ob-

through the air, which is the act of flying; but no one phrase to express motion on the ground; the last-named motion being included in such terms as the acts of walking, running, leaping, etc.

tained by the action of the long flexible tail rather than by the limbs. In the frog the gill-arches indeed disappear, yet even here the anterior limb remains of small size.

In mammals the relation existing between the motion of the anterior extremity and the respiratory act must be remembered. It is not accidental, I am sure, that such an extremity is placed at the side of the front of the thorax. The act of breathing is assisted by many of the muscles which move the anterior extremity, whereas none of the posterior have any connection with respiration. The posterior extremity, on the other hand, is held to the line of the spine by a fixed pelvic girdle. The exceptions to this rule are so unimportant that they can not be separately treated. Not only is each hip bone fixed to the side of the trunk, but is also joined to its fellow at the pubis (bats often excepted, and seals always), and the relations of both bones are held to be, not with respiration, but to the functions of the organs of the abdomen, especially to the rectum and the organs of generation.

We have seen that the shape of the limb is in relation to the density of the medium through which it is used, and now we will notice that in terrestrial forms the motions of the limbs hold an equally exact relation to the center of gravity of the body. In the most rapid motion of the terrestrial type the front limb can retain its plane of support on the ground until the trunk has passed along so far as to bring the center of gravity in a line which will pass vertically upward through the foot. In a subsequent attitude of support the hind limb can reach forward as far as or even beyond this line.

It is a remarkable circumstance that both in the anterior and posterior feet the ground is reached by the outer border of the foot, and not, as one would suppose at first sight, by the foot being brought down in a horizontal position. In all quadrupeds the outer border of the leg and the outer border of the foot receives distinct nerves. In the fore limb it is the ulnar, in the hind limb it is the musculo-cutaneous and short saphenous nerves. The outer border is further often adorned with fringes of hair or other appendages either in the form of scutes, warts, or of special folds of skin. In a word, the outer border of the foot and leg, taken as a whole, is apt to be distinct from the rest of the body, not only in the way it is used in progression, but in its domination of nutritive processes.

The cycle of movement of the foot in the act of walking is something as follows: The foot in the first stage—that is, before being brought to the ground—is in a position midway between pronation and supination. The outer border as it reaches the ground is held in this position but for an instant, since the body surging forward by the aid of the other three legs soon brings the main lines of weight upon the foot, which now rests on its widest surface of contact. The impact is somewhat gradually transferred to the inner border, along which, when the main body weight is beyond, the foot is lifted from the ground.

It is noteworthy that when used in any other way except for support on the ground (I mean by this, firm contact against a resisting terrestrial surface), limbs of all mammals resemble one another; for example, forms so distinct in systems of classification as the sloth, the bat, the seal, and the duck-mole are associated in one respect—namely, by the absence or diminution of impact of the several parts of the limbs. The characters of the bones of the arm and thigh, since they do not support the body on the ground, are almost exactly alike in the sloth and the bat. In like manner the general outline of the scapula in man, the ape, the kangaroo, and the jumping mouse conform to a single plan—that is to say, the suprascapular fossa is narrower than the infrascapular—since in none of these animals is the anterior extremity used for support. Likenesses which are due to strain, as in the bat and sloth, are recognizable; as well as those due to adaptation of the anterior extremity to prehension, as seen in men and the apes; or those due to adaptation to the swimming habit in creatures so far apart as the duck-mole and the seal; but all these, nevertheless, may be associated by a merely negative character—namely, the absence of impact.

When walking with a closed umbrella, using it as a cane, one brings the ferrule down on the ground at every step. A leg of a living animal periodically adjusted to the ground like the closed umbrella is said to be modified by *impact*. In a word, it is impact that takes place

in the umbrella every time it is brought to the ground. When the umbrella is held in mid-air and opened, the movement is independent of impact. An animal using its anterior extremity in a similar manner (as in a bat unfolding its wings for flight), the several parts are said to undergo *strain*. The difference between impact and strain in a general way implies a difference in the method of progression—that is to say, the difference between strictly locomotor and prehensile use.

I will now attempt to make an application of the above-stated facts, which I fear some will think radical. I allude to the study of the causes of certain fractures in the human body. May I venture the opinion that without an understanding of the mechanism of the limb in the lower animals the aetiology of lesions of the limb in man can not be explained? The following is an example of a lesion through strain: A sailor falling from the deck of a vessel to the bottom of an open hold, catches at a rope for support; he sustains himself but for an instant; he feels a sharp pain in the region of the shoulder; he lets go his grip and again falls. Examination shows that he has fractured his shoulder blade.\*

Now, the man has done exactly what a monkey will do many times a day in the forest, as he springs from swaying vine to pendent bough; but the animal incurs no risk to the shoulder blade or to any other bone. The man has attempted something, in an excursive way, to which his structure appears to be adapted, but in the attempt he fails and incurs injury. Unless an analysis of such a lesion can be reasonably undertaken by comparing the manner in which this act can be safely performed with that which results in disaster—in a word, of a comparison of the parts in a monkey and in man—no exact clue to the fracture can be vouchsafed. Let me also invite your attention to a lesion by impact. Sir Charles Bell has drawn the figure of a man on a stumbling horse; the man is in the act of being thrown forward. The position of the anterior limb of the horse and that of the arm of the man are the same. In an instant afterward both limbs will come to the ground, the horse's to enter into the second stage of the foot's normal cycle, the man's to break. In placing his anterior extremity forward as though it was well adapted to move on the ground (though it has long since been adapted for an entirely different class of work), he applies it for a purpose to which it is in reality unfitted, and disaster ensues.

I have been interested in studying the position of the hand in fracture at the lower end of the forearm. The text-books teach that the hand comes to the ground directly in the middle, or on the thumb side. I have concluded, when the body falls prone, that the hand comes down on the little-finger side, as is normally the case in the lower animals. An examination of the specimens preserved in museums has convinced me that this assumption is just as capable of explaining the deformation as is any other, and is sustained in addition by an examination of its literature. A short time ago I stumbled and fell. I instinctively threw the right hand forward to break the force of the fall. I found when I examined the parts that my hand was bruised along the little-finger side, and the clothing soiled on the corresponding part of the forearm. In the explanation of a lesion, created as it is by an error of impact, the line of reasoning essential to it is quite different from what is met with in strain; but the problem suggested is like it in one regard, that it is profitable to the study of the manner by which the parts of a limb adapted for strain are easily disadjusted when called upon to perform the duties of impact, and also like it in another way that it can be best explained by a knowledge of comparative anatomy.

**The American Medical Association.**—The committee appointed at the last meeting to consider the best means for promoting the prosperity of the sections of the association will hold an adjourned meeting in the Hotel Cadille, Detroit, Mich., on June 6th, at 3 p. m. Members of the committee are requested to notify the chairman of their intention to be present at this meeting. The committee would esteem it a favor if each member of the association would communicate in writing his or her views concerning the best measures for promoting the development of the sections. Such communications may be sent to the chairman of the committee, Dr. John S. Marshall, No. 9 Jackson Street, Chicago.

\* Dr. Joseph Leidy. *Proceedings of the Philadelphia County Medical Society*, 1891, p. 73.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. Walter Wyman, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for March 18th:

CITIES.	Week ending—	Population, U. S. Census of 1880.	Total deaths from all causes.	DEATHS FROM—									
				Phthisis pulmonary.	Yellow fever.	Small-pox.	Varicella.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.		
New York, N. Y. ....	Mar. 12.	1,515,301	919	102				8	31	31	18	8

**Parisian Surgery.**—In one of a series of articles entitled Clinical Notes in the Paris Hospitals now appearing in the *British Medical Journal*, the writer, Mr. Ernest Hart, who is the editor of that journal, says:

The leading surgeons and professors of the French hospitals have the advantage, for the most part, of very complete arrangements for teaching; the complete control of a highly skilled staff of *internes*, who serve for three years, and when they are professors of the Faculty, of *chefs de clinique* of thorough training and proved high accomplishment (who serve for five years); their own operation theatre attached to their wards, in which they perform a whole series of operations on their clinical days, uninterrupted by the intervening operations of any other surgeons. There is a staff of nurses and dressers trained to the methods and special views of the surgeons, so that whatever there is of individuality in the views and methods of the operator, and whatever is special to him in his dressings and instruments, may always be found thoroughly carried out. The surgical services, too, are generally larger and more active than those in the London hospitals; and the training of the surgeons who have passed through a long course of competitive examinations extending up to, and often beyond, the age of thirty, and even into middle life, has accustomed them to the art of teaching in a logical and systematic manner. As a rule, in an active surgical clinic, half a dozen operations may always be seen performed in succession, and each of these is illustrated by a short preliminary discourse, explaining the grounds for the diagnosis, the surgical and anatomical relations, and the steps of the operation about to be performed; at each stage of the operation, and while operating, the surgeon explains his procedure, or any modification of it which he finds necessary to adopt; and at the close of the operation he describes the result attained, and comments on the course of events. The French hospital surgeon or professor is trained to this end from his earliest career. Unless he is capable of lucid, orderly, and thorough exposition on almost any subject within the range of his art, he can never hope to survive the numerous competitive trials of the kind which he has to pass through at each successive grade of appointment, from that of *interne* to *chef de clinique*, *chirurgien du bureau central*, *agrégé*, etc. No man who was not laborious, studious, conscious of ability, and capable

of the rapid improvisations and dissertations required at every stage, would embark on a career which demands an average of at least ten to fifteen years of continuous work and preparation, and even then only the fittest survive. So that the surgeons, lecturers, and professors can at least all of them operate, lecture, and teach with approved skill and trained powers of exposition and large resource in acquired knowledge of the academic as well as the practical kind.

The surgical service of M. Péan, at St. Louis, is one of the most active in Paris, and his operating days in the amphitheatre attract a large number of students and of practitioners whose attendance is rewarded by a fluent and instructive clinical commentary as well as brilliant operations which include methods of proceeding, many of them invented and most of them modified by this able and eminent operator. On the day on which I was present in the theatre of St. Louis in the middle of the Christmas vacation there were fewer students than usual, but the cases for operation were as usual numerous, and the whole proceedings were sufficiently characteristic of the special features of the clinical and surgical teaching in the operating theatre to make me think that a pretty full report of the day's work would be of interest as illustrative of a highly instructive method of operation and of demonstration.

**To Contributors and Correspondents.**—The attention of all who purpose favoring us with communications is respectfully called to the following:

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desire to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Original Communications.

THE  
DIAGNOSIS OF PANCREATIC DISEASE.\*

BY JOHN S. THACHER, M. D.

THE unsatisfactory position which the pancreas holds in the minds of clinicians is indicated by the scant attention which the best modern works on clinical medicine give to the consideration of its diseases. Fagge's book does not discuss the subject at all. Strümpell gives thirty lines to the symptoms and diagnosis of the various diseases of the pancreas, and Flint gives fifty. Briscoe, in one of the most recent English text-books on medicine, says that "very little of clinical value is known about the diseases of the pancreas, and it would be a waste of time to discuss their diagnosis." Friedreich, in von Ziemssen, says that "the pancreas does not possess any function the suppression of which would produce appreciable symptoms." This being the position of the best representatives of the profession even up to quite recent times, while indicating a conspicuous need, it would discourage us from any attempt to clear up our ignorance in this direction, were it not that several interesting observations have recently been made bearing upon the subject.

The pancreatic functions which are best understood are the digestive functions, and indeed until very lately these were the only ones which it had been even suspected of. Of all the digestive fluids the pancreatic juice is the most important, doing a greater work upon a greater variety of food elements than any of the other fluids of the alimentary canal. It would seem, then, that any disease of this organ, interfering with the production of this juice, would promptly and conspicuously manifest itself, and we would expect to find proteids, starches, and fats appearing undigested in the *feces*, and the patient's general nutrition distinctly interfered with. But both clinical and experimental observations on this point disappoint our *a priori* expectations. As regards starch, while Abelmann's studies upon a dog whose pancreas had been removed indicate a marked diminution in the digestion and absorption of starch, yet there are enough cases pointing otherwise to make Leo briefly dismiss the subject with the words that "the digestion of starch is in no way affected by the absence of pancreatic juice."

As regards proteids, there have been some experiments and some clinical observations showing that a pancreatic lesion may lead to the presence of abundant meat fibers in the *feces*. But the experiments of Müller and clinical experience seem to teach us that Leo is right in saying that "the effect on the digestion of meat is not sufficiently marked and constant to be of any value for the diagnosis of pancreatic disease." In the fats we have something to which most clinicians have pinned their faith as about the only reliable

indication for the diagnosis of these diseases, and it can not be denied that in several cases an abundance of fat has been passed from the rectum, and certain experiments, notably those of Abelmann, point in the same direction; but the basis of the belief in this diagnostic point has, on further observation, become much weakened. As Leube states, "an unusual abundance of fat in the *feces*, which one would expect in all diseases of the pancreas, and especially in total degeneration of the gland, is usually not found." Or, as Leo puts it, "it has been shown that the view often heretofore expressed, that an absence of the pancreatic juice from the alimentary canal produces an abundant presence of fat in the *feces*, is incorrect."

There have lately appeared the detailed reports of several interesting experimental observations upon the absorption of fats from the alimentary canal, and the influence upon this of the pancreatic juice and the bile, with quite uniform testimony to the predominating influence of the bile, leading us to an opinion that if there be simply an absence of the pancreatic juice from the intestines, while the bile is normal, the absorption of fats will ordinarily be complete.

The experiments of Müller show that where the bile is cut off from the intestines, while the absorption of starch and proteids is very little or not at all affected, the absorption of fat falls from about ninety per cent. to between forty-five and twenty per cent., and, on the other hand, that in the absence of pancreatic juice the absorption of starch is not affected, the digestion of proteids is a little less complete, and no effect upon the absorption of fat could be established.

Munk's experiments on a dog with biliary fistula show a great diminution in the absorption of fats; and, again, the experiments of Dastre, while showing a slight diminution in the absorption of fat in the absence of pancreatic juice, show a more marked effect in the same direction from the absence of the bile. Moreover, in none of the cases of pancreatic cyst collected by Treves did fatty dejecta occur, and according to Grandmaison they are observed more often in cancer, which is generally close to if not involving the duodenum, than in other pancreatic disease. Taking these facts into consideration, and also the fact that lesions of the pancreas are often associated with obstruction of the biliary duct, it seems possible that in many of the cases where fatty dejecta have occurred, they may have been due to shutting off of the bile rather than to the absence of pancreatic juice.

Our practical clinical conclusion, then, as regards the presence of proteids, starch, or fat in the *feces* as a basis of diagnosis, must be, that while they may occasionally occur in cases of pancreatic trouble, and when occurring in abundance would be one factor in the diagnosis, yet they usually do not occur, their absence does not by any means indicate a normal condition of the pancreas, and the presence of fat would point more strongly to some trouble of the liver or its ducts.

One point, however, associated with this, is perhaps on its way toward establishment, and that concerns the dimin-

\* Read before the Hospital Graduates' Club, at its fifty-fourth meeting, November 19, 1891.

ished ratio of the fatty acids to the neutral fats. Müller has shown, from three cases, that the ratio is in diseases of the pancreas diminished from the normal eighty-four per cent. to forty per cent., and Leo says that "the saponifying power of the pancreatic juice is distinctly affected, which gives us the only means of positive proof that the pancreatic juice is not doing its part in the intestinal digestion." This point, however, loses largely from its practical value because of the necessity of elaborate quantitative tests which could not be undertaken except by an experienced chemist.

A further practical point has recently been suggested, and possibly further observations will show it to be well taken. Walker maintains that the presence of the pancreatic juice is necessary to the normal pigmentation of the fæces, and that the absence of this juice, as well as the absence of the bile, may produce clay-colored stools.

This is based on two cases. In the first case the patient had light-colored stools without jaundice, the liver on autopsy being normal and the ducts pervious. But there were epigastric pain and diabetes, there were fatty fæces, and at the autopsy the pancreas was found much enlarged, fatty, and fibrous. In the second case the patient had had stone-colored stools, without jaundice or other symptoms of liver trouble, it and its ducts being normal at the autopsy; but there were greasy dejecta, also glycosuria, and at the autopsy the duct of Wirsung was found involved in the cicatrix of an ulcer.

The point suggested to Walker by these cases he also supports by certain further considerations. In the first place, the coloring matter of the bile is not the same as that of the fæces, and is therefore altered chemically by some agent, possibly by the pancreatic juice.

Again, as Claude Bernard observed some thirty-five years ago, "the bile only colors matters a very light yellow, while with the pancreatic juice the bile takes a decided brown tint."

Again, meconium, which contains bile, does not, however, show the usual fæcal color, and it is known that the pancreatic juice does not flow until after birth.

And again, certain drugs which increase the fæcal pigmentation and relieve symptoms of indigestion, are shown by experiments not to increase the secretion of bile.

While these cases and arguments of Walker's can hardly by themselves force us to accept the suggestion based upon them as proved, it seems to be sufficiently worthy of consideration to be borne in mind in suspected cases for further demonstration or disapproval.

Before leaving this discussion of diagnostic aids based on the digestive functions of this gland, let us notice this further point which has been made by Piseni.

The pancreatic juice effects the change of proteids into peptones, and of these into leucine and tyrosine, from which, by decomposition, are produced skatol, phenol, and especially indol, which latter is in turn the source of indican. From this it would follow that pancreatic disease would lead to the diminution of indican in the urine.

Piseni's experiments show that ligation of the pancreatic duct reduces the indican of the urine to a quarter of its normal quantity; but, as Leube states, "since human urine

in normal condition contains so scant an amount of indican, its absence from the urine or its presence in traces is only of diagnostic value in cases where, from the nature of the attack, an increase of the indican in the urine was to be confidently expected"; or, as Leo puts it, "since tumors of the stomach and intestines are generally accompanied by a marked increase of indican, an epigastric tumor is probably pancreatic if the indican is not increased or is diminished."

Lipuria has been mentioned as a symptom of diseases of the pancreas, but this is certainly so rare as not to merit our attention.

Until quite recent times, experiments have revealed no further functions of the pancreas than the digestive ones; but during the few years just past both experimental and pathological observations have been rapidly accumulating which now oblige us to admit at least the very plausible showing in favor of a further and important office for this gland.

It is true that even in the last century the coincidence of diabetes with pancreatic affections was noted. But Bouchardat was the first to propound a theory of the pancreatic origin of diabetes. Lanceraux, later, supported this position vigorously. But it was not until the experiments of Mering and Minkowski, reported in 1889, showed that total extirpation of the pancreas was followed by all the characteristic symptoms of diabetes, that the idea of an essential connection between this organ and this disease began to be generally and seriously entertained.

Of twenty-one dogs upon which they operated, three died within twenty-four hours without urinating; the other eighteen all excreted sugar, and the condition after complete removal of the pancreas was "not a simple temporary glycosuria, but a genuine diabetes mellitus, resembling in all respects the most severe form of this disease in man, even to extreme hunger and thirst, marked polyuria, emaciation, and weakness."

Lépine also extirpated the pancreas from several dogs, and found that in all those in which the autopsy showed complete removal there was marked and increasing glycosuria.

Dominicis has done thirty-four extirpations with less constant results, and yet, of these thirty-four animals, twenty-one had glycosuria, and all showed progressive emaciation, polyuria, polydipsia, and polyphagia, with various affections of the skin.

Remond's experiments included total and partial extirpation and ligation of the excretory ducts, and in each set he sometimes obtained and sometimes failed to obtain glycosuria.

Hedon has operated on twenty-three animals. The first ten died promptly, but improved technique resulted in the survival of the other thirteen, and they all passed glucose in their urine.

Arthaud and Butte also report similar results. They say: "We have repeated the experiment of total removal of the pancreas, and we have obtained results absolutely identical with those reported by Minkowski and von Mering and afterward by Lépine."

Renzi and Reale reported to the Tenth International Congress that in their experiments total removal of the pancreas was followed, in seventy-five per cent. of the cases, by glycosuria, and made the further interesting announcement that diabetes could be experimentally produced by removal of the duodenum or of the salivary glands.

It is of interest that incomplete extirpations have often failed to produce glycosuria, a remnant of little more than one tenth of the gland being enough in some cases to avoid this result, recalling analogous experiences with myxœdema after thyroidectomy.

The experiments which we have just reviewed conflict, it is true, with many former experiments on the pancreas, but they were largely ligations of the ducts, and the attempted extirpations were many, possibly most of them, incomplete. If, for instance, we look over Martinotti's reports of the operations from which he drew his decidedly negative conclusions, we find that remnants of the organs were revealed in three of the four cases, and that in the fourth, where none was left, no examination of the urine is reported, but there was marked emaciation.

Klebs and Munk failed to obtain diabetes by ligature or excision, and referred the diabetes observed by others to lesions of the solar plexus. But Klebs has since expressed his adherence to the pancreatic explanation; and, moreover, Peiper's cases of solar-plexus extirpation from fifteen animals, of which eleven survived, showed no diabetes.

Experimental observations are then very emphatic in support of the causative relation of pancreatic lesions to diabetes.

Nor are post-mortem observations silent on this question. Saundby's carefully detailed reports of the changes in the various organs of fifteen cases of diabetes in man which came to autopsy, show that the most constant and marked was an atrophy of the pancreas, being present in seven of the fifteen, and in all of the typical wasting cases. In four others the gland was firm and fibroid, and in only four did it appear normal.

Baumel professes to have found either gross or microscopic lesions in all the cases of diabetes which he has investigated. And Lanceraux reports twenty consecutive cases of the severe wasting variety, his "*diabète maigre*," which have come under his observation. Of these, fourteen have died, and they have all shown abnormal conditions, obstruction of the ducts, sclerosis, or steatosis. Frerichs reports thirty cases, of which twelve showed an abnormal atrophy. Senator says that one half show pancreatic lesions; and various others have recorded isolated cases illustrating the relation.

My own experience regarding this question has been this: During my connection with the Presbyterian and St. Luke's Hospitals, five autopsies have been made in those institutions upon well-marked cases of diabetes. To these I will add a case from Dr. Draper's practice, in which I examined the organs, and a case in which the autopsy was made by my associate, Dr. Tuttle. These include all the cases clearly of this nature which have during this period come to autopsy within the range of my direct investiga-

tion, and in all seven distinct pathological conditions of the pancreas were found.

One was of about one third the normal size, with a flabby atrophied appearance on gross examination. Another was so atrophied that only minute traces of the glandular tissue could be found. Another was of about two thirds the normal size, with apparently an increase in the interlobular connective tissue. Another was of about half the normal size, firm, and containing hardly any gland tissue except in the head, the rest being only dense connective tissue. Microscopical examination showed an extreme increase in the connective tissue at the expense of gland tissue, a good deal of proliferative endarteritis, and in places large numbers of infiltrated leucocytes. Another was a little larger than the usual size of a pancreas, but, on microscopical examination, showed a distinct, though not very abundant, increase of connective tissue, considerable degeneration of the gland cells, and a marked invasion of the gland by adipose tissue. Another, while not appearing small on gross examination, showed under the microscope extreme invasion by adipose and much increase of connective tissue, while the last case had dilated ducts which contained numerous calculi, the tissues being cirrhotic and atrophied.

In two cases not included in this group the patients were under observation for only six and twenty-four hours—one in coma all of the time and the other a considerable part of the time, so that no histories were obtained; but there was sugar in the urine, and yet the pancreas showed in each case but very slight, perhaps I should say doubtful, lesions.

On the other hand, I have examined the pancreas from a large number of miscellaneous cases, and while slight changes of the kinds related above are sometimes met with, still it is rare to find even a trace of any pathological abnormality.

It is true, on the other hand, that very many cases of pancreatic disease show no sugar in the urine. Of Fitz's seventy cases of acute and suppurative pancreatitis and pancreatic hæmorrhage, in only one is sugar reported—a very small proportion, even after allowing for the many whose urine was probably not examined because of the brevity of the attack or for other reasons.

Treves's collection of pancreatic cysts were accompanied by glycosuria only "sometimes," and it seems to be in but a small minority of cases of cancer of this organ that the symptom is observed.

And yet, considering all the experimental and pathological observations, we seem forced to respect the idea of a causal relation between pancreatic disease and diabetes, and to admit that for diagnostic purposes diabetes is of some value, pointing to be sure rather to chronic pancreatitis, lithiasis, cirrhosis, degeneration, and steatosis, than to tumors or acute lesions.

Of the suggestions offered to explain how the glycosuria follows from the absence of the pancreas, the most interesting, and the most reasonable in the scant light as yet thrown on the subject, is that which supposes a normal glycolytic ferment produced by the pancreas, thrown into the circulation and necessary to the utilization of glucose.

The blood, when no longer supplied with this, would evidently find itself overloaded with sugar, which it could no longer dispose of. The experiments of Lépine and others bearing on this theory make very pleasant reading, but the interesting nature of the recent observations already described have led us far enough in the discussion of the glycosuria symptom.

Pain in the epigastrium is generally present in acute lesions, often severe and of a colicky or neuralgic character. It is sometimes spoken of as cœliac neuralgia. In the case of cysts the pain is usually slight; in cancers, not, as a rule, prominent; in cases of lithiasis or chronic inflammation it is generally absent; and is probably never caused by steatosis or atrophy.

Jaundice is frequently produced by cancer of the pancreas, as would be expected from the intimate relation between the common bile duct and the head of the gland, and often helps to locate an epigastric tumor. It is rarely produced by cysts, and not at all by the other pancreatic lesions.

Ascites and enlargement of the spleen are frequently caused by the pressure of a cancer upon the portal vein, but not by a cyst or by other lesions.

It should be borne in mind that hæmorrhages into the intestine and stomach sometimes occur when the pancreas is diseased. It has been recorded in some cases, and I have happened to see two instances of hæmatemesis due to cancer of the head of the pancreas. In each case the tumor had invaded the wall of the duodenum, producing ulceration, from which the hæmorrhages are supposed to have come.

Compression of the abdominal aorta, with or without pulsation, is an occasional symptom of pancreatic tumor.

Compression of a ureter is rare.

The skin is said to be sometimes bronzed; it is occasionally dusky or yellow.

As regards further indigestion symptoms, there may be loss of appetite, nausea, eructations of gas, a sense of fullness in the epigastrium, and diarrhœa or constipation. Mental dullness and depression are common.

In acute lesions, in addition to the severe pains already mentioned, there are apt to be vomiting and collapse, sometimes fever. A slowing of the pulse is sometimes noticed, particularly in cases of hæmorrhage, and in these, too, death usually comes very quickly, often instantaneously.

Physical examination for a pancreatic cancer has failed to find it in about half the cases, though the gland can sometimes be felt even when normal. When found, it is in the epigastrium, at the mid-line or a little to the right of it, and is, as a rule, very slightly or not at all movable.

A cyst occupies the same position, but is often large, may fill the abdomen, and is generally immovable, round, with distinct outline, tense and elastic, but fluctuation can not always be made out. It usually enlarges rapidly, and has been known to discharge itself into the intestine.

The cyst fluid is generally turbid, brownish, odorless, of rather high specific gravity, alkaline or neutral, and contains albumin, but no urea and no bile. It will generally, but not always, emulsify fats and change starch into sugar.

## TREATMENT OF ACUTE OSTEOMYELITIS.\*

By ELLSWORTH ELIOT, JR., M. D.,  
ASSISTANT SURGEON IN THE VANDERBILT CLINIC;  
ASSISTANT DEMONSTRATOR OF ANATOMY  
IN THE COLLEGE OF PHYSICIANS AND SURGEONS.

In the treatment of surgical affections, as in the treatment of all medical troubles, one should always endeavor to eliminate the cause of the disease.

When for any reason this can not be accomplished, our treatment, conducted on purely symptomatic principles, becomes ineffectual. Nature may come to our assistance and restore the patient to health, with full return of all the patient's functions; but, although this happy result is moderately frequent in certain medical diseases, it must be admitted by all that unskillful treatment in surgery too often leads to a tardy convalescence, temporary, and at times permanent, loss of function or serious deformity, with perhaps the loss of a limb, and occasionally even loss of life itself.

Of no disease is this more true than in acute osteomyelitis, and in calling your attention to its treatment it will not be inappropriate to consider briefly its cause and the resulting pathological condition.

For years before bacteriology played its present important rôle in pathological surgery, acute osteomyelitis was considered an infectious disease simply from the resemblance of its symptoms to those of diseases whose infectious character was undisputed. Bacteriological investigation has substantiated this fact, and to-day at least two distinct forms of micrococci—namely, the *Staphylococcus aureus* and *Streptococcus albus*—have been found, both separately and together, in osteomyelitic exudations. These have been cultivated in suitable media, and have, by inoculation, reproduced in animals a pathological condition similar to that existing in the primary disease.

Undoubtedly these organisms gain access to bone through the circulation. Why they should attack this structure in preference to other organs is not clearly understood. Various authors mention a "*locus minoris resistentiæ*," indicating by this term that certain portions of the body offer less resistance to the onslaught of germs than others, every part of the body being equally subjected to their attacks. Certainly, whenever the integrity of bone is disturbed by traumatism, that particular portion is more likely to become the seat of an osteomyelitic process than any other part of the bone. Then, too, in children, who are most frequently subject to this disease, the primary foci are found near the epiphyseal line, and surely this part of the bone, being constantly in an active state of development, is less capable of resisting the attack of germs than other more perfectly organized portions, for the blood-vessels in the epiphyseal vicinity are imperfectly developed and afford more abundant facilities for the lodgment and collection of germs than do similar channels in perfectly vascularized bone. When the inflammatory process is once excited by the presence of these germs its onset is severe and its course is rapid. This is readily accounted for by a

\* Read before the Hospital Graduates' Club, December 17, 1891.

consideration of the normal anatomical peculiarities of bone, together with the virulent qualities of the micrococci.

Bone, to fulfill its function of support, must be practically unyielding. Consequently the walls of the cavities that contain the blood-vessels are inexpandible. The exudation resulting from the inflammatory process through the walls of these blood-vessels collects between the bony, unyielding wall of the cavity and the yielding wall of the blood-vessel. The force exerted by this exudation soon overcomes the counter-resistance of the arterial pressure in the nutrient vessel, the lumen of which gradually diminishes in size, until finally the blood ceases to flow through it, and that part of bone to which it imparts nutrition dies. This process of disintegration is still further assisted by the comparatively poor anastomotic circulation that exists in bone. To be sure the vessels in the Haversian canals communicate freely, but this is more of a capillary net-work, and is totally inadequate to supply any particular part of a bone which has been deprived of nutrition by the inflammatory process.

It is not, therefore, surprising that acute osteomyelitis, beginning near the epiphysis, should rapidly involve the major portion of the shaft of a long bone, and, on the other hand, it is very fortunate that the epiphyseal cartilage, owing no doubt to its lack of vascularity, should act as a barrier, and so prevent the inflammatory process from involving by contiguity first the articular extremity, and subsequently the joint structures themselves; and it is also very fortunate that after the soft parts immediately overlying the inflamed bone are involved, the capsular ligament of the different joints attached to the bone within the epiphyseal line should, in virtue of its strength, resist the disintegrating character of the inflammatory process, now at its height in the soft tissues, and exclude it from the joint proper.

There is one joint in the body, and that a very important one, which proves to be an exception to this general rule. I refer, namely, to the hip; and it is not difficult to explain this exception if we consider the attachment of the capsular ligament and its relationship to the epiphyseal line. In front this ligament is attached to the spiral line running around the inner aspect of the upper extremity above the lesser trochanter, and behind it is attached along a line at the junction of the outer third and inner two thirds of the posterior surface of the neck, including in its attachment, therefore, the head of the femur, the epiphyseal line, the entire neck in front, and posteriorly the inner two thirds of the neck. Hence any inflammatory process near the epiphyseal line, in extending outward, must soon reach the synovial membrane that lines the inner surface of the capsular ligament and the bone itself within the above limit, and necessarily involve the joint in a suppurative, infectious process. The treatment of this, in itself a most serious condition, demands special consideration, and will be discussed subsequently.

But, although, as we see, the involvement of the joint nearest the focus of inflammation does not usually take place by contiguity, yet in a certain number of cases this same joint, or even others more remote, may become swollen, their synovial cavities filled with a serous or at times

even with a purulent fluid, and subsequently the whole joint may become seriously involved in destructive inflammation.

This condition is readily explained by the fact that the micrococci, having found a favorable soil for development, are multiplying rapidly, and are being carried in constantly increasing numbers by the circulation to the different parts of the body. Whether joints, to which by this way they gain access, become involved, depends upon the kind of micrococcus. It can be incited artificially more frequently with the streptococcus than with the staphylococcus, but as an attack of osteomyelitis is usually due to both of these germs acting together, the occurrence of joint inflammation in this disease is not unusual.

If severe cases remain untreated, the occurrence of metastatic abscesses in the different viscera, especially in the kidney, may result from the lodgment of micrococci in these organs.

With this understanding of the cause of osteomyelitis, and of the serious consequences that may result, it is not difficult to formulate a rational method of treatment which may be applied to the great majority of cases.

In the first place, we should endeavor to prevent a possible attack by suitable prophylactic measures. In all exanthemata and other infectious diseases, when convalescence is established the patient should not be allowed to walk until a considerable interval has elapsed subsequent to the fall of the patient's temperature to normal, and afterward, when walking, the patient should be careful not to subject himself to any blows or contusions, either from coming in contact with furniture or from possible falls, from too sudden exertion, or from any cause whatsoever, no matter of how trivial a character.

When, however, prophylactic measures are not successful in preventing an attack of acute osteomyelitis, or when a case presents itself, apparently spontaneously, without known cause, the proper method of treatment may be a subject of dispute. Some advocate the expectant plan of treatment. Applications of poultices are advised, with absolute rest in bed. Usually the administration of a brisk cathartic follows, and then a general waiting-for-development policy is pursued, which usually means waiting for the soft parts to become involved in suppuration.

It must be said, however, that this general plan of treatment is only employed by practitioners in that class of cases where obscure symptoms make the diagnosis difficult, and that, either when the diagnosis is easy or has been made by skillful men, the radical method of treatment is usually preferred. The expectant plan of treatment is the oldest, and was very generally employed in pre-antiseptic times when operations of all kinds were dangerous; superseded by radical measures, it still shows its influence upon the treatment of this disease, in that surgeons are inclined to wait one, two, or three days before proceeding to operative interference. Delays are dangerous, and more especially in acute osteomyelitis, where every additional hour means just so much more necrosis in the early stages and greater liability to general septic infection in the later stages of the disease. Consequently, now that antiseptics has removed the danger of incisions, it would certainly be a ra-

tional procedure to perform an exploratory operation at the outset, in place of waiting for the symptoms to become of such a marked character that the diagnosis no longer remains doubtful.

If, after such a procedure, the diagnosis is confirmed, further operative means should be resorted to to prevent the death of the bone and the infection of the system. The main indication for treatment may be expressed in one word—namely, drainage, with, if possible, the removal of the original focus of inflammation.

This is accomplished with either a trephine or a chisel, by means of which, as soon as the periosteum has been divided and reflected to one side, the medullary cavity, as well as the cancellous spaces between it and the surface of the bone, are thoroughly exposed by an opening at least an inch long and a quarter to half an inch wide, according to the normal dimensions of the bone affected. This opening should be made in that part of the bone where the inflammatory process is most intense, for the reason that the original focus is situated in this part, and it is desirable that this focus should be removed with a Volkmann spoon, or, at all events, that it should have a free exit, and so be enabled to come away with the discharge as soon as the process of ulceration has separated the dead from the healthy bone beneath.

Great care should be taken that this opening is made close to and on the shaft side of the epiphyseal line, but not through it, in order that the natural growth of the bone may not be disturbed, which, as is well known, depends for its increase in length upon the epiphyseal cartilage.

One or more similar openings may be made at some distance from this, the essential one, in the inflammatory area, but the intervening portions of bone need not be removed, as such a procedure might lead to unnecessary weakening of the bone without insuring any better result. The cavities thus exposed should be well irrigated with a strong antiseptic solution, preferably the bichloride of mercury, and packed loosely with iodoform gauze—the wounds being treated openly. After the application of a heavy Lister dressing, the whole limb should be kept absolutely at rest by immobilizing the joints both above and below the bone involved.

By this means the exudation that has collected outside the walls of the blood-vessels, in the Haversian canals, readily flows into the antiseptic dressing, carrying with it a large number of the micrococci. The blood-vessels, relieved of an enormous pressure, once more are permeable. The bone receives its usual nourishment, and thus practically a "resolution" takes place, except in those portions of bone which, having been deprived too long of their blood supply, are dead and must separate gradually from the healthy bone before granulations can be formed and the process of repair be completed.

The integrity of the epiphyseal cartilage also is preserved by this radical treatment, and the growth of the limb continues undisturbed when convalescence is established. This is of paramount importance, for deformity would surely result if this epiphyseal layer of cartilage were destroyed

and the bone ceased to grow. The degree of deformity depends upon the bone inflamed, and also upon which extremity of this bone is involved. In the humerus or femur disintegration of the cartilage causes merely shortening of the corresponding limb. Inasmuch as the growth of these bones depends chiefly upon the epiphyseal cartilage in the upper extremity of the humerus and the lower extremity of the femur, the amount of shortening with destructive inflammations in this vicinity is very much greater than in case of involvement of the opposite ends of these same bones.

In the bones of the forearm and leg the growth of the corresponding limbs depends upon the development of the cartilages in the upper extremities of the tibia and fibula, but the lower ones in the radius and ulna. Consequently, if any portion of these bones entering into formation of elbow and ankle joints, respectively, are involved, the growth of the limb is but slightly retarded; but if the opposite extremities to those above mentioned are involved simultaneously, the growth of the limb is seriously curtailed. If one extremity alone is involved, and this is the rule, the unaffected bone continues to grow, and very marked lateral deformities of wrist joint, especially, may render the hand useless and demand surgical interference for its relief.

After the primary operation the subsequent treatment of the wound is conducted on ordinary surgical principles. If the disintegrating process has been so extensive as to result in a fracture of the bone, the limb must be immobilized until, after the subsidence of the disease, new bone is formed and firm union takes place between the broken fragments. With the destruction of a large portion of the shaft of a long bone, immobilization must surely be enforced until sufficient new bone is formed to enable the part to resume its normal function without danger of fracture. Ordinarily an interval of from several weeks to as many months must elapse before the bone in which the inflammatory process has occurred can resume its normal function.

In addition to the surgical treatment that we have just described are several indications that demand medical means for their relief. In the earliest stage of the disease pain is not only a very prominent symptom, but also a very disagreeable one, which requires the exhibition of an anodyne, preferably morphine. The patient should naturally be in bed, on a fluid diet, and some benefit may follow the use of various antiphlogistic remedies.

After operative measures have relieved the condition of tension in the bone, the subsequent discharge from the wound is most profuse. Large dressings, with abundant absorbent cotton, are usually well soaked at the end of thirty-six to forty-eight hours. Such a drain upon the patient's system, especially if it exists for any time, must necessarily be followed by rapid progressive emaciation, and demands some supportive treatment, preferably the administration of malt and sherry, in generous amounts, several times daily. The dose can gradually be decreased as the discharge becomes less abundant, and finally stopped altogether when the patient fully regains his lost strength.

In no place in the body is the importance of early oper-

ative interference more clearly demonstrated than in the treatment of acute osteomyelitis of the neck of the femur, near the epiphyseal line. I have previously alluded to the anatomical reasons which render the involvement of the hip joint an absolute certainty, and it is only by an early operation that this can be prevented.

In this class of cases we endeavor to remove the inflammatory focus before the destructive process incited by it has reached the surface of the bone. If this can be accomplished, the periosteum may be preserved, while the inflammatory area is removed *en masse*, and, after new bone is formed, the joint will resume its normal function of support, with, in all probability, a certain amount of stiffness, the operation consisting practically in a subperiosteal resection of the head of the bone. If, however, the periosteum is found in a necrotic condition and bathed in pus, the most thorough removal of the dead bone, with subsequent drainage and irrigation, combined with rest, will alone save the limb, and, after a tardy convalescence, the head of the femur, if not actually dislocated, will be held in place by the comparatively weak support of strong bands of connective tissue, the result of the process of repair.

Unfortunately, in neglected cases, when septic symptoms have developed, our treatment can only be supportive. Large doses of stimulants, with antipyretics, are administered, and certain patients, especially those with a strong constitution, may eventually recover. Such a fortunate termination is very exceptional, and, inasmuch as death does occur from a general infection of the system, certainly that plan of treatment should be followed that has for its purpose the elimination of the micro-organisms that cause the trouble, when these are localized and before they have an opportunity, after great increase in number and under undue tension, of entering the general circulation and terminating the life of the patient.

## MASSAGE AT RAPID OR VIBRATORY RATES.

BY GEORGE H. TAYLOR, M. D.

THE prevailing idea that massage is necessarily manual in mode of application, and therefore limited to the motory resources of a masseur, is an error that has served to restrict the study of the most beneficent phases of this medical recourse. The chronic invalid, even the very feeble, has receptive capacity for rates of massage far beyond that of the medium and comparatively neutral scope of manual power. We have seen that rates of massage much *slower* than the hand can supply corresponds to certain spontaneous or auto-processes of the vital organism, and that these slow rates therefore comply with fundamental therapeutic requirements. But to secure the proper rate, and to adjust its applications to parts of the body difficult of access, mechanism is necessary. This shows that therapeutic advantages may be derived from sources which, without mechanism, are incapable of being even tested. The remedial capabilities of slow massage being thus rendered available in therapeutics, naturally suggests the possibilities which may lie hidden in untried higher rates of the same agent

waiting to be tested, studied, and exposed to professional judgment and service.

Massage at rapid rates—those beyond the limits of the hand to execute—likewise requires the intervention of mechanism for the purpose of multiplying the *rate* of the motor processes. Mechanical adaptations are also required to adjust the applications to the different regions of the trunk and extremities, to adapt the degree of the force to special curative requirements, and to give instant control of the action, especially as regards degree, to the person to whom it is applied, for only by this provision can he always derive agreeable and no other sensations from the applications.

Quick massage is simply *vibration* of the fleshy mass receiving it, without reference to its form, degree, or source. The essential peculiarities of vibration are shortness of the linear extent of the motion, and the consequent frequent reversal of its direction. This causes very numerous *endings* of the motion, which returns over the same line. Vibration may be compared to the blows of an infinitesimal hammer, under continuous and very rapid action. To show the significance, physical and physiological, of this mode of delivering energy is the purpose of the present article.

Apparatus suitable for communicating vibration, quick massage, to the body and its parts admits of considerable variety of form. The physical nature of flesh, being soft, yielding, and elastic, permits vibratory waves to pervade its mass. The action is propagated in flesh as it is in fluids, and reaches all its innermost parts at the same rates and in nearly equal degree. Such applications are by no means superficial. Structural parts, cells, membranes, fluids, whether interstitial or coursing in different directions in appropriate channels, vital organs, and non-vital ingredients are pervaded alike by this agency.

The vibrations thus mechanically transmitted to the vital system are lost only in appearance, being, in fact, changed without loss to other forms of energy, and subject to identification by other tests than the direct senses. Both the vitalized and the non vitalized ingredients encountered by this agent present fields for its transformation. As the motion of a meteor, on striking the atmosphere, becomes not only retarded but changed to its equivalents, so does the motion transmitted to tissues, on being retarded therein, become changed in *several* ways, according to the nature of the ingredients obstructing its pathway.

The study of the effects of vibration or quick massage becomes of interest from the following separate and distinct considerations:

It is of *scientific* interest to determine just what equivalent forms of energy arise in the vital organism under the different forms and rates of vibratory action, and what conditions, on the part of the organism, serve to promote, restrain, or modify its physical effects.

It is of *physiological* interest to determine whether the different classes of vital functions may be increased, transposed, or diminished by means of directing motor energy from outside sources to their respective vital organs. Also to determine whether such transformed energy is identical in form with that developed by the organism, and whether

that arising from the two sources is capable of becoming merged and physiologically undistinguishable.

And it is of high *medical* interest to determine the *consequences* of the effects of vibration above suggested in pathological states of the organism, the therapeutic values derivable therefrom, and the conditions and cautions necessary for rendering such therapeutic influences practical.

It hence appears that a wide and almost virgin field for exploration is opened by the proposition to subject the vital organism and its non-vital constituents, its diverse functioning activities, and its varied incorporated and spontaneous chemical tendencies, to the influences flowing from transmitted vibration.

The difficulties which this study has presented have arisen chiefly from the fact that the inquirer is very apt to seize upon some *one* effect or fact, and neglect others even more worthy his attention. It shall be my endeavor to place before the reader such facts as seem to establish *principles* available for the physician. The nature of the case does not permit of a strictly scientific order in the arrangement of the subject; the topics embraced therein will therefore be presented in the order of the presumed interest of the inquirer.

*Vibration as an Anæsthetic.*—This agent is somewhat known as a means for securing the suspension of pain, and even for permanently removing chronic neuralgic affections which have proved intractable to other remedies. Notwithstanding the well-proved efficacy of this agent, its restricted use for this purpose is easily accounted for by the fact that facilities for its proper administration are not usually at hand, and the necessary practical details are unfamiliar to the physician. Most physicians have seen references to the efficacy of this agent in their reading, especially of English medical periodicals of a dozen years ago. In these days of prevalence of neuralgic disorders and of much seeking of remedies adapted to ameliorate if not to obviate pain, this effect of vibration is entitled to renewed consideration, and a just estimate of its nature and value should be acquired. Is this special remedial effect temporary or permanent? Is it to be classified with the so-called sedatives, or with some heretofore imperfectly investigated class of remedies?

Different investigators have arrived at radically opposite conclusions respecting the remedial effects of vibration in painful nervous disorders. Some have accepted the easily demonstrated fact as a fundamental principle; others regard suspension and even the radical cure of pain as secondary and dependent on certain changes superinduced in the ordinary physiological activities, which are neglected by the sedative-seeking inquirers. These differences are doubtless due to prepossession of opinions or their absence on the part of the investigator. Experimenters are apt to find what they are seeking, especially when the search is obscure. Very much depends on the kind of instruments employed, and their adaptation to determine the facts sought.

A better understanding of this interesting subject may be attained by bringing forward some of its historic as well as its scientific particulars. Medical literature is indebted

to Dr. J. Mortimer Granville, of London, England, for setting forth his experience and conclusions in a book published in 1884, entitled *Nerve Vibration and Excitation, or Stimulating Percussion for Functional Nervous Disorders*. The applications are described as light, rapid blows of a *percuteur*—a small hammer with an ivory point, which, under the reciprocating motion imparted to it, transmitted vibratory action to the skin and flesh underneath. The operator's hand was evidently the source of power in the earlier experiments, but irregularities of rate and degree, and the very limited time it was possible to sustain the action, rendered the effects uncertain, and so clockwork mechanism, operated by a spring, was substituted. The apparatus while in action was moved about upon and near the painful region, and therefore communicated rapid waves of vibration to the flesh underneath. There is no statement of the vibratory *rate*. The action was frequently interrupted by necessity for rewinding the machine, and irregular from the varying force of the spring. A small electro-motor was, in a few instances, substituted for the spring, but no hint of its superiority appears, or that the conclusions previously made were in any way modified by this motor recourse.

The purpose in view in these vibratory applications was avowedly the single one of *arresting pain*. There was absence of expectation of other effects, and such others as necessarily accompanied the suppression of pain were quietly ignored. A long array of cases of neuralgic and other painful chronic affections, successfully treated by vibration, are given in support of the claim for the therapeutic power and efficacy of this agent.

Dr. Granville engaged the attention of several physicians of eminence, among them Sir Hugh Campbell, who repeated the experiments, apparently without attempting any variations, and added confirmation to Dr. Granville's views. At about the same time similar experiments were conducted by M. Boudet and M. Vigoureux, of Paris, leading to the same conclusion; not, however, without a vigorous dispute as to priority of discovery of what was regarded as a remedial principle. Readers of the medical literature current a dozen or more years ago will doubtless retain some memory of these discussions. Most remarkable is the unanimity with which these inquirers *excluded* all consideration of other effects of the agent whose powers they examined, except the single one of suspending *pain*. They did not even intimate that sensations of an *agreeable* kind are also suspended by the same agent.

The above statements respecting the control of pain in chronic affections by proper applications of vibration (or quick massage) are fully supported by my personal experience in employing this agent for the class of invalids mentioned. This experience, it is due to say, has unquestionably been more extended and varied than those which have above been referred to. This statement will, I hope, be sufficient justification for presenting facts additional to those with which the medical profession is most familiar, and which lead to far different as well as broader conclusions respecting the nature and effects of the agent under discussion.

Dr. Granville and his associates adopted a theory respecting the nature and effect of vibration which is best explained in words quoted from his book, written for this purpose. He says: "All nerve action is vibratile . . . the neuralgic state consists essentially in an abnormal set or series of vibrations into which the nerve has been thrown, perhaps by cold, or a mechanical or chemical irritant. This state may be changed by mechanical vibrations, propagated to the nerve sheath and its contents." Again, "we deal with the nerve and *not* with its surroundings"—an evident mechanical impossibility. "No force is communicated by the hammer of the *percuteur*." What, then, is communicated? "The sole effect of vibration is to excite the centers and call out their potential energy, converting it into kinetic force. It can act only through the nerves." "Vibration, artificially supplied, introduces discord into the rhythm of the morbid vibrations of the painful state, and a change that brings relief," etc. Dr. Granville's subsequent difficulties in securing the desired relief of pain by this means ought to have shaken his faith in the theory, for he says: "Great care and tact are necessary in treating pain by vibration." "By continuing the process too long, *painful* vibrations may be set up"; hence directions are given to approach the painful region *slowly*, first subjecting non-painful, contiguous parts to the process—details of cases being given in which the non-success of previous treatment was changed to success by adopting this change of method.

If these investigators had reflected that it is physically impossible to vibrate nerve tissue separately from its surroundings; that the *other* tissues and the fluids included in a fleshy mass exceed, according to trustworthy authorities, by a *hundredfold* that of the nerve filaments it includes; and, further, that the fluid and solid, organized and unorganized, vitalized and non-vitalized, contents of the mass include ingredients strongly predisposed to chemical changes—that, in fact, such changes, either normal in consonance of physiological purposes or in opposition to those purposes, are inevitable—these factors would undoubtedly have influenced their conclusions.

Historical accuracy, the curiosity of the reader, and possibly justice, unite in requiring that certain *dates* be here recorded. In a correspondence, claiming priority over Dr. Boudet and the French claimants of the "discovery" of the pain-relieving power of vibration, Dr. Granville says: "As a matter of fact, nerve vibration by percussion with instruments furnished by myself was tried at the National Hospital, in Queen Square, London, in January and February, 1878, these trials having been led up to by previous experiments by less satisfactory methods."

My personal investigations of the destiny of vibration in the vital organism, and the physiological and therapeutic effects flowing from this agency, assumed practical forms in 1863-'64, and very soon led to diversifying the mechanism whereby the effects may be varied and duly tested. The conclusions drawn from my experience were embodied in my article in the November, 1869, number of the *New York Medical Journal*, entitled *Inquiries relating to the Therapeutic Effects and Uses of Vibratory Motion*. The succeeding

March number of the same journal contained a second article, a sequel to the above, entitled *On the Use of Force as Vibratory Motion in the Treatment of Diseases of the Nerves*. My book, bearing a title nearly identical with that of Dr. Granville's book, was published in 1870.

The foregoing account of transatlantic experiments determining the anæsthetic effects of vibration proves the detrimental influence of preconceived theory in the recognition and appreciation of facts. The experimenters, in discovering what they sought, neglected to observe facts of even greater importance. No evidence is shown that nerve energy is vibratory in its development or transmission; or that, if vibratory, such form of action bears any relation to that of any mechanism. No allusion is made to ultimate nutritive sources of nervous energy; to its possible deterioration from nutritive faults; to the consequences of imperfect *denutrition*, for nutritive waste is even more liable to defects which react on the sensorial powers than nutritive supply; of suffering caused by maldistribution, as well as from faulty development of nervous powers; of impressions of the consciousness from general and local excess, as well as from insufficiency of nervous energy—all of which are topics inseparable from that of pain, its modifications, suspension, and remedies.

My purpose in devising means for subjecting the organism and its parts to vibration was less that of subduing pain than that of reaching the nutritive sources of pain by an adequate remedy. It seemed to me that the disagreeable and the painful impressions of the consciousness which invalids experience *may be legitimate*, denoting either faults of nutrition in the parts to which the undesirable sensation is referred, or obstacles in the line of sensory conduction. It is also notable that *pain* is intimately connected with appreciable defects of the other forms of energy which the vital organism coincidentally develops, all of which depend on nutritive processes as their sources. True remedies therefore must extend to the fundamental seat of energy, to the tissues wherein its distinctive forms are assumed. It follows that to correct morbid impressions in the seat of the consciousness, it is essential to rectify the nutritive source whence they spring, which, as we all know, may or may not be in nervous tissues.

Now, nutritive acts necessarily include two considerations, both of which are equally involved in the consummation of the nutritive purpose, whatever the function or the tissue concerned in the nutrition may be as a whole. Nutrition implies the supply of ingredients *to*, and the removal of the same *from*, the local point at which energy is evolved or other purpose complied with. Nutrition is far from consisting of accumulation of substances, vital or otherwise; it implies an equal amount of outflow or *denutrition*. The first is largely associated with *motor* physics; for the latter, *chemico*-physics are indispensable. The supply and convoy of ingredients to the vital arena are of no account, while the changes due their elemental constitution are unprovided for. In fact, the controlling phase of nutritive purpose is the *denutritive*, chemico-physical excluding process. Now, since the energy for conducting these indispensable factors of nutrition is in health developed

within the organism, and since defects of health are manifested in these factors, the suggestion of re-enforcing them by direct supply of energy from exterior sources when their insufficiency becomes apparent arose very naturally.

This suggestion is strengthened by direct experiment which any one commanding sufficient manual dexterity may repeat and verify. By widely separating the fingers of the right hand so that when a smart blow is given the stroke of each finger falls distinctly separate, the rate of the impact or percussion is quadrupled, and vibratory waves are made to pervade any fleshy part subjected to the process and may be felt at its opposite side. In a proper case for vibratory treatment not only is pain abated, but the accompanying soreness and swelling also. On account, however, of the impossibility of *sustaining* the required rate of motion, the recourse described is impracticable.

Two direct effects of vibration serve to explain the salutary consequences of its application to the vital organism. One of these is the contribution it affords in aid of the defective *motor* physics of the physiological system; the other is the ready and abundant contribution it brings in support of the *chemico*-physics of the organism whenever this department of physiology is faulty—a department whose defects are the chief concern of the average therapist.

How the mechanical or motory purpose is served by vibration is so obvious, even to the superficial inquirer, that but little explanation is required. The motor energy communicated from the exterior travels *as such* in the fleshy parts. But flesh is pervaded by conduits streaming with fluids (blood) in directions predestined by the mechanism of organization. The local aspect of chronic disease is marked by areas of *detention* of these fluids, by local mechanical obstructions, and by defective operation of the causes to which the outflow of these fluids is due. Now, *vibration* affords a succession of impulses *direct* to the contents of the vessels, urging them forward in the several directions required, thus becoming an effective auxiliary to pre-existing causes of the circulation. The same cause also restores the natural contractile powers of the circulatory vessels, and these causes unite in impelling forward whatever mechanical obstacles these motory defects may have superinduced, or which previously existed.

The consequences of outflow of the contents of obstructed vessels are immediately apparent in surrounding parts. Fluids of whatever quality, normal interstitial juices and those loaded with morbid materials, return directly to the venous vessels to become resubjected to the corrective chemistry of the organism as a whole.

Important as these effects may be considered therapeutically, they are in reality the least of those superinduced by vibration.

These experiments and observations were begun in 1862-'63, and soon led to others through amplified means and diversified methods. The physiological inquirer is not content with generalizations; he insists on specific tests for the facts he seeks. He submits each tissue, secretion, function, or other object of investigation to separate and to conjoint experiment, and thus assures himself of the circumstances which influence the behavior of each part and of

each to all. The mechanical scope of the human hand was evidently too restricted, and incapable of bringing further facts to light; its narrow field has been occupied and understood for ages, and is comprised largely of motor physics. What other important relations of therapeutic significance might be opened by a survey for which mechanism is required remained to be developed.

*The Mechanical Apparatus.*—A proper investigation of the higher rates of motor energy or vibration requires apparatus capable of complying with the following particulars:

It should transmit vibration at variable but known rates to any selected part of trunk and limbs.

It should impart this action in diversified forms.

It should be capable of limiting the action and its effects to designated parts while other parts are omitted.

It should be capable of confining its action to distinct classes of functioning tissues.

It should be operated by adequate and untiring sources of mechanical power.

In pursuance of these purposes above outlined, I constructed (1864-'65) the several pieces of apparatus shown below. The first (Fig. 1) imparted rapid alternating mo-

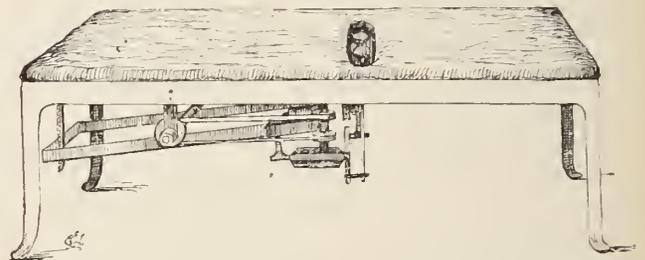

FIG. 1.

tion to two *percuteurs* in close proximity, which act upon any part exposed to them by means of necessary mechanism through an opening in the couch upon which the patient rests. The position of the patient is shifted at will, or as may be agreeable, and the *degree* of the impulse is controlled by the patient.

The *percuteurs* are set in action by a very short crank, rapidly revolved by a multiplying wheel, operated by a light motor or by hand or foot power.

The most effective rate for this and other forms of mechanism for similar purposes was found to be in the vicinity of a thousand waves or strokes a minute. Diminution or entire suspension of pain was a pretty constant effect, provided the conditions before stated were complied with. The term then thought to afford a satisfactory explanation of this effect was *revulsion*, which referred to its mechanical rather than its physiological scope. Experience, however, brought to light other reasons for considering this term a proper one.

Fig. 2 represents a form of apparatus made at this time in which the effect of impact or percussion upon the nerve centers through surface impressions is *wholly eliminated*. Even a much larger amount of motor energy may be transmitted than by the apparatus shown at Fig. 1, but entirely without percussion and the effects arising therefrom in either

the reflex or the sensory nerves of the part. The nerves of the skin, and for a distance regulated at option beneath it,

FIG. 2.

are neither impinged upon nor traversed in the application of this process. The apparatus imparts very short, perpendicular motory excursions to the fleshy mass compressed against a very soft elastic pad. The mechanical conditions are such that the pad grasps the flesh, which moves as a whole, while interaction of distinct anatomical parts is mainly prevented. The superficial nerves therefore wholly escape mechanical disturbance, and they convey no impressions to the nerve centers. Nervous irritability becomes suspended while the muscles, or at least their deeper portions, are subjected to passive motions in the direction of the axes of their fibers. In short, muscle action, and consequently muscle nutritive changes, are in this way incited in opposition to nerve incitation and its consequences. This effect is nearly the reverse of that caused by No. 1. For distinction, this consequence of this application may be called *functional revulsion*. The evidence of this effect is shown by diminished or suspended pain and inclination to sleep, effects which increase day by day as the treatment is pursued.

FIG. 3.

attention to the part which is to receive it.

A similar process can be applied to the arms, legs, and even the trunk, by including either of these parts between

two pads to which reciprocating action is given. Fig. 3 shows the application to the arms of this form of vibration, the effects of which are intensified by pressure. The pressure is given by means of a lever under the hand of the patient and under instant control. Relaxation of pressure diminishes or suspends the action. It is perfectly safe to leave the control to the option of the recipient, the feelings in this case being a safe guide. The double pads do not increase the rate, but insure contact of molecular constituents, and thus secure the transformation of motor to other forms of energy. In this case also the superficial endings of nerves are neither traversed nor impinged upon, as in Fig. 1, but other functional processes are incited, to be subsequently explained.

Vibration is transmitted to parts of the organism by still another method, which may be called *oscillating*, and is readily understood by reference to Fig. 4. A foot is snugly held by an appropriate device at the end of a shaft, which, by suitable mechanism, is made to oscillate on its axis. The bone of the leg, being practically a continuation of the shaft, participates in the same action to which it in turn subjects the flesh and the fluids of the limb. A similar device (Fig. 5) applies to the hand and arm.

FIG. 4.

FIG. 5.

In this use and form of vibration (the same rate as before stated being preserved) both percussion and compression are eliminated. It follows that the effects of vibration are secured in such a manner that nervous impressions are entirely absent, and all nerve functions—either afferent, efferent, or central—are in abeyance.

The principal effects inure to the morphological elements, and especially to the chemical phase of all the constituents of the parts. Motor energy encounters various orders of resistance, compelling it to assume other and different forms.

The above are samples of many forms of apparatus devised by me at the period above referred to for transmitting motor energy in vibratory form to parts of the vital organism, and which enabled me not only to determine approximately what forms were assumed by it under different circumstances, but also what physical, physiological, and therapeutic effects were superinduced, as well as the positive and relative value of these effects in differing pathological states.

*The Chémico-physics of Vibration.*—The foregoing de-

scription of apparatus affords a necessary preparation for understanding what is clearly the most important effect of the transmission of motor energy to the vital tissues, whether considered in its physical, physiological, or therapeutic aspect. For the attending conditions are such that the motor energy of the vibration is largely transformed to *chemical* activity, and results in elemental changes and transpositions of matter in conformity with physiological purposes.

These effects also accord with the purposes of therapeutics, especially in chronic cases. Cures are largely sought through remedies which have been proved by experience to re-enforce the chemical phase of physiological activity, or which naturally tend to increase this form of action. This ultimate principle appears whenever the operation of remedies in the cases referred to is fairly analyzed, and is sustained by experience, however empirical.

Pathology, whether its manifestation be general or local, is easily understood to have its source in some form or degree of *incompleteness* of the chemical phase of physiology. For it is only through this cause that injurious ingredients, tending to retrogression and to impair the vital structures and processes, can be retained by the vital organism to exert their destructive influence. And the correctness of this assumption is proved whenever the chemical phase of physiological activity is properly and judiciously promoted.

Primarily, vibration consists of very short motory excursions between two endings or turning points. The motory force is resisted by whatever it meets or collides with at these endings; at these points the motor energy is imparted to whatever objects or ingredients may be present to receive it. Each distinct wave-ending is therefore comparable to the blow of a light hammer; and vibratory applications become the continuance of such infinitesimal blows, having the shortest possible intervening time. The energy expended at each impact is taken up by the atomic elements of the ingredients thus forced into intimate relations.

While blows of a hammer develop heat and rend cohesion, those of the *percuteur* and the other vibratory methods described are expended under radically different circumstances. The collision between ingredients of complex chemical constitution and of extreme instability is produced. The component atoms of these ingredients are very unlike in their nature, and are therefore receptive of the suddenly imposed energy in different degrees. The inevitable consequence is a destruction of the weak chemical equilibrium, and a new distribution of chemical affinities resulting in new compounds less unstable in chemical character. In short, the effect of vibration in vital structures is largely chemical, arising from the transformation of *motor* to *chemical* physics, and the reduction of unstable, therefore incomplete and injurious products, whatever their source in the organism, to physiologically completed and therefore normal and innocuous products which find immediate egress.

The school lecture-room affords abundant and apt illustrations of the principle above stated; as when phosphorus is made to ignite when the motion of a rapidly revolving

wheel, to whose periphery it is attached, is suddenly stopped; and when gun-cotton, nitroglycerin, and many similar bodies are exploded by sudden arrest of motion or concussion, although, perhaps, capable of burning on being ignited in the ordinary way.

These are apt illustrations, derived from inorganic chemistry, of what occurs in the vital organism under similar conditions—namely, that forceful contact is even more provocative of chemical change than any other circumstance; that the development of chemical energy is simultaneous with the disappearance of motor energy; that unstable compounds subjected to chemical change from this cause are inevitably reduced to more stable forms; that vital energy arises coincidentally with the passage of an unstable body from a state of *more* chemical energy to one of *less*; that unstable ingredients, in becoming stable, are rendered indifferent, consequently innocuous; that the vital endowment of matter in affording protection against the influence of chemico-physics is equivalent, for the time, to chemical stability; and that vibration or concussion of elements secures the extreme degrees of chemical products contemplated in the physiological purposes.

Turning now to the vital organism, we find in it a most admirable field for the physical processes and for insuring the physical consequences above indicated. Its components are exceedingly heterogeneous, and the differing classes of ingredients are largely diffused. The vitalized components are, for the instant, under protection of vitality. The non-vitalized are in various orderly stages of resolution. Everywhere are residual or *waiting* ingredients, and everywhere imperfectly and improperly employed materials, in which chemical reduction is due and in which chemical change is inevitable. Whether such change be in the progressive physiological order, or become disorderly and deteriorative, is determined by the extent and the degree of the chemico-physics whose influence is brought to bear on the impending act. All components of the vital organism occupy stages of a career; all are passing forward to the next stage; and all are predestined to the chemical change which signalizes the evolution of either heat or other form of energy. Pathology is necessarily associated with imperfect fulfillment of the chemical change wherein energy is liberated for the advantage of the individual.

*Oxygen, its Uses by the Vital System, and what determines its Consumption.*—Of the oxygen introduced by the respiratory process from the unlimited and ever-ready supply afforded by the atmosphere in which we dwell, just so much is taken in health as is required by the chemico-physics of the organism. Food of all kinds has definite composition; the completed products of its chemical change which pass from the vital system are also definite in composition, but increased by the exact amount of oxygen taken from the air of respiration.

The purposes of oxygen in the vital system thus become clear, and the consequences of its defective use by the vital system are intelligible, although the pathological states which the physician is called upon to correct are often referred to some intermediate circumstance which has little to do with the use or non-use by the vital system of oxy-

gen. *Why* the system takes up less of this ingredient than is required to dispose of its waste and superfluous ingredients is seldom inquired. The pathology which arises from faults of use being attributed to secondary causes, other than direct remedies are apt to be chosen for its correction.

There has, indeed, been a vast amount of experimenting based on the therapeutic need and artificial supply of oxygen, thus palpably connecting its defects with pathology. Among these devices is that of increasing its proportion in the air respired; that of condensing by pressure the air for respiration; that of liberating oxygen from chemicals in the air respired and in the digestive organs; that of increasing the air space in the chest by developing its muscles, etc. These methods only promise increase of *supply to, not use by, the system* of this element—things very different in practice. These devices all prove disappointing, not only because the supply thus afforded is necessarily temporary while the need is continuous, but more emphatically because *none* of these devices are capable of supplying the thing wanting—that degree of chemico-physical action which insures the appropriation by the unstable residuals of the system of the oxygen which, though present, remains unappropriated.

Oxygen is appropriated at all points where heat or other form of energy is disengaged, because, under these circumstances, the systemic ingredients are passing into higher and usually into emergent forms of oxidation. It is clear that both motory physics and chemico-physics are required to secure the effect desired; the one to transport ingredients to the several points of use; the other to effect the forceful contact whereby motory is transformed to chemical energy by its transfer to the elementary constituents of the changing materials.

These effects arise spontaneously in health, and, though appearing to be causeless, are, in fact, intimately associated with the involuntary and the voluntary motory functions. The first have also the reciprocating form, and in the arterial department, which conveys oxygen on its being demanded, approaches the vibratory rate, while the voluntary motions seem to incite and perfect the involuntary.

The therapeutic uses of vibration consist, therefore, in securing such higher degrees of perfection in the faulty activities of the organism as shall remove the consequences of previous defective mechanico-physics and chemico-physics. The effects of applications of vibration extend primarily to the oxidizable ingredients, whatever be the name of the affection of which such ingredients are a fundamental factor. For reasons stated, those ingredients of the blood, interstitial fluids, and solids which possess the highest instability are the first to become destroyed on forcible contact with the oxygen, always in readiness for this physiological purpose, and always effective when the conditions prescribed in the organic mechanism are complied with, whether these be classed as hygienic or remedial.

The substantial reason now appears why vibration allays pain and proves a trustworthy remedy in chronic neuralgias and other painful affections. This agent, by promoting physiological oxidation, removes the essential *cause* of pain, so far as this depends on impressions received by the nerv-

ous system from morbid environment. The pain is *not* the disease; local or general; it is the evidence of the presence of unstable ingredients, embarrassing nutrition, compromising the development of energy in other forms, defeating organic purposes, and affording timely warning of a severer fate. Pain is the disagreeable consciousness superinduced by these and similar physical circumstances. It is *these*, rather than the notification of their existence, which should be removed.

The vital system necessarily at all times contains *intermediate* products in various stages of progress toward the final goal of the physiologically perfected stage of oxidation, which stage is represented mainly by carbonic dioxide, water, urea, and salines. Faulty conditions diminish the degree attained by the oxidizing process; and the intermediate products, well known to chemical investigators, necessarily increase, and thereupon assume abnormal and morbid phases and strange chemical forms. The discharge from the system of the above-named perfected products is diminished, but their equivalents are retained in some noxious form, awaiting bettered conditions, which shall render them inoffensive.

If we may consider chronic neuralgia and other painful affections as resulting from the impressions the nerves and consciousness receive from the presence of adventitious ingredients inimical to vitality, the morbid condition may be understood by the term *auto-poisoning*, and bears an analogy to the poisoning arising from accumulation of oxidizable ingredients accidentally or willfully ingested. The effects of alcohol, opium, ether, and the alkaloids and sedatives in general will answer for illustration. Experience proves that the most trustworthy remedial recourse in these cases is to promote and to intensify physiological oxidation by maintaining the respiratory process by every means available till the poison, if the dose be not too large, is neutralized by oxidation. The effect of vibration proves that the same principle is practically available for removing the cause of chronic neuralgic pains, and the rapidity and certainty of this effect indicates that oxidation, the cessation of pain, and the production of heat are synchronous in the part subjected to the process.

*Other Physical Effects of Vibration and their Physiological Consequences; Heat.*—It is clearly provable by many conclusive tests that heat-production is very much increased by vibratory applications. The glow of warmth produced in the skin, soon reaching the previously habitually cold extremities, affords satisfactory evidence of this effect. The temperature of the body, however, never rises above the normal standard, since the regulative powers, having their seat in the nervous system, are in effective operation. The increased heat becomes equally diffused; in part because the circulation is also diffused, but in greater part because the process of heat development is no longer limited to the central parts, but is restored in normal degree to peripheral parts.

The rapid restoration of heat by vibration arises from two causes. One is the direct transformation of the motor energy to heat by *friction* of anatomical components of the organism—the fibers and membranes, down to the minutest

morphological ingredients, being compelled, by the motory waves, to glide with pressure upon each other—as when a piece of rubber is repeatedly stretched, or even rubbed, it becomes heated *without* chemical change. The other cause of heat arises from chemical acts arising from the increased consumption of oxygen.

The sources of heat are the muscle cells, whose rate of heat development is greatly quickened by vibration, even though the motor function be suspended, and also the non-vital fluids which pervade all tissues. These contain unstable and highly oxidizable ingredients, which only wait a due impact or collision of elements to be rendered stable, and necessarily yield heat in the act.

The evidences of therapeutic oxidation are patent to the least scientific observer. These are of two kinds. One is the palpable increase of *completed* products of oxidation, whose emergence is due to the process. The urine becomes increased, assumes its natural odor and color, and ceases to yield a precipitate on cooling. This change is due to diminution of *extractives*, another word for the various products of defective oxidation. The quantity of watery vapor transpired and exhaled is likewise sensibly increased, as we know must happen, since water is part of the product of the resolution of the same ingredients that also afford the urea and carbon dioxide which is disengaged.

The *other* class of evidences consists of positive appeals to the senses. These are indications through the feelings and the muscular powers of returning health, the most significant of which is subsidence of pain and increase of volitional manifestations of energy, mental and physical. The mutuality of these relations appears to imply that *pain* is at the expense of the energy-evolving functions—that such energy requires guidance, not abatement or destruction; in short, that the central idea of remedying pain, legitimately, should be that of affording it more useful, and therefore agreeable, scope, through other than nervous channels of expenditure.

The principle of *transferring* manifestations of energy from one to another functioning seat, which I have above shown to be practicable, is invested with deep scientific and physiological interest, since it appears to open the way for radical change of therapeutic purposes. The desire to *suspend the consciousness* of disagreeable impressions, instead of abolishing their source, has greatly increased the number of drugs whose principal claim of merit is the possession of this power, which experience proves to be liable to enormous abuses. The practicability of changing painful to agreeable manifestations of nervous power by rectifying the nutritive source whence such powers emanate naturally supersedes, to the extent the method is practiced, the demand for drugs whose chief value lies in preventing painful impressions from reaching the powers of the consciousness.

Vibration, aside from the mechanical and chemical physics it introduces, is, however, entirely capable of *suspending* pain and the sensory powers of any local portion of the body. This effect appears to arise from the fact that when a part is subjected to vibration, its sensory nerves, each and all, thereby receive *exactly the same* impression. No differences exist and none are perceptible. The dis-

criminating power of the consciousness is therefore abolished, because the effect of impressions is abolished, and with it feeling, both agreeable and disagreeable, including local pain. The fact stated is easily proved to the most incredulous, who is at liberty to adopt other reasons than those assigned. The well-attested effects of what is called *hypnotism*, in respect to pain, may be susceptible of similar explanation. The vibratory subject does not, however, need to have a special susceptibility. It is probable that this incidental effect of vibration arrested and held the attention of the transatlantic investigators referred to in another part of this article.

We may now briefly review some of the physiological and therapeutic effects superinduced by quick or vibratory massage:

1. Vibration may be so applied as to impress the sensory nerves principally. This is when the impingement is on the skin. By this means the nutrition of sensory nervous tissues, conductors and centers, is increased, and therefore their product of sensory nervous energy. This effect is easily carried to a morbid degree, to the detriment of other functioning parts.

Vibration may also be so applied as practically to *omit* the nervous sensory tissues. In this case the motory physics, but more especially the chemico-physics, of the vital organism are increased, while the excess of nerve nutrition and the irregular, obstinate, excessive, and morbid manifestations of nervous power are thereby diminished and permanently remedied. This effect of vibration has extensive application in nervous affections and the chronic diseases which are the usual accompaniments of nervous diseases.

2. The remedial effects of vibration are by no means restricted to functional diseases. Its chief sphere is in the motory and chemico-physics of the organism. The curative powers of this agent, through reduction by oxygen of injurious ingredients which spontaneously arise from faults of what may be called motory hygiene, require personal investigation by the inquirer, to be understood or entitled to belief.

Vibration is not exercise, and, since the will is not engaged, causes no fatigue. The rate of vibratory motion is incompatible with muscular nutrition, which requires a slower rate.

3. Vibration may be regarded as *specific* in all chronic inflammations of whatever part of the organism, and whatever may be the morbid product developed therefrom.

The several effects of vibration which are conjoined in producing this remedial consequence may be noted. One is thorough *diffusion* of the circulation—increasing the amount of blood at will in any desired region of the body, and correspondingly diminishing it in other regions, especially in that suffering from inflammation. The caliber of the capillaries is increased and contracted, in compliance with the disposition of their contents. Another is the urging forward, *from* the affected region, the obstructive contents of capillary vessels, including both morbid chemical and other materials, thereby allowing interstitial, effused materials to return to the circulation, and so to remove the

swelling. A third effect is the submission of these morbid ingredients to the chemico-physics of the organism, while this function is exalted to high efficiency by the addition from motor energy. Intimately connected with these is the modification of pulse-rate. The rate is *never* quickened, and in all cases of abnormally high pulse the rate is diminished—in pulmonary affections to the extent of fifteen or twenty beats a minute, and often this effect becomes permanent.

## GONORRHOEA OF THE RECTUM.

A REPORT OF THREE CASES.

BY JAMES P. TUTTLE, M. D.,

LECTURER ON RECTAL DISEASES IN THE NEW YORK POLYCLINIC.

SINCE the famous experiments of Bonnière, showing the comparative immunity of mucous membranes covered with cylindrical epithelium from blennorrhagic infection, the existence of gonorrhœa of the rectum has been seriously questioned by many observers. The discovery, by Neisser, of the *Bacillus gonococcus* has, however, put to rest all contention upon this point. It is not my intention here to discuss the subject of gonorrhœa of the rectum, but simply to report three cases of the disease. They were all observed in my clinic for diseases of the rectum and anus at the New York Polyclinic, and were seen by several members of the classes during the past two years.

CASE I.—M. R. appeared at the clinic on April 10, 1891. He complained of pain and burning about his rectum, frequent desire to go to stool, and inability to sleep, on account of the intolerable itching at the anus. The stools, he said, were sometimes solid, but usually composed of thick mucus. He confessed to the practice of sodomy, but thought that had nothing to do with the case. The anus and the contiguous surfaces of the buttocks were red and swollen. The anus was not funnel-shaped, and the mucous folds were not obliterated. The parts were bathed with a muco-purulent discharge, and there were several little cracks in the muco-cutaneous border, resembling fissures. The rectum was hot and tender to the touch and covered with a slimy-feeling secretion. Through the speculum it appeared red, inflamed, and bathed with a thick, yellowish pus. There were no ulcerations observed, and no hæmorrhoids whatever. Microscopic examination of the pus, after straining, showed Neisser's gonococcus in abundance.

The method of collecting the pus for these examinations being of importance, it may be described here. The anus is wiped off as gently and thoroughly as possible with absorbent cotton, and then washed with a solution of salicylic and boric acids—Thiersch's solution. An O'Neil's speculum is then introduced closed, and the sliding bar on the upper side is withdrawn, the patient lying on his left side. The specimen is then taken from the surface of the rectum, and not from the discharge which flows down into the speculum, lest by any chance some of the secretion from the anus should have been carried up on the end of the speculum. Several specimens are then examined, to corroborate one another, and to avoid, as far as possible, the error of mistaking disease of the rectum for that of the anus. The solutions used for staining in these cases were gentian violet and ammoniated carmin, and the results were practically the same with both.

The treatment in this case was by injections of bichloride of mercury (1 to 20,000) and the separation of the inflamed but-

tocks by a pledget of lint dusted with a powder of oxide of zinc and starch, equal parts.

The patient made a good recovery after four weeks' treatment.

CASE II.—F. S., aged twenty-three, presented himself at the clinic on November 10, 1891, complaining of pain, itching, burning, and occasional hæmorrhages in the rectum. He has too frequent stools, and has noticed of late a small lump on the edge of the anus. He confesses to habitual sodomy, and has had a discharge from the rectum for several weeks. There are two small condylomata about half an inch from and posterior to the muco-cutaneous border of the anus. The anus is infundibuliform, the sphincters are relaxed, and the mucous folds are obliterated. The rectum is hot and tender to the touch; through the speculum it appears red, swollen, and rather excoriated than ulcerated in patches of considerable area. The pus was not very thick, rather of a creamy yellow, and not very profuse. The patient said it had decreased of late. The pus cells contained gonococci.

The condylomata were removed with the scissors and their bases cauterized with nitric acid. The rectum was then irrigated, by means of my rectal irrigator, with a saturated solution of boric acid. The advantages of this irrigator are its cleanliness and the facility with which a constant stream of fresh solution can be passed through the rectum without wetting the couch, while at the same time it distends the folds of mucous membrane so as to cleanse and medicate them.

This patient made a good recovery in ten days.

CASE III.—D. K., aged twenty-one, a domestic, came to the clinic on February 12, 1892. She complained of severe pain in the rectum, with itching and burning. She denies pæderasty, but confesses to illicit intercourse. She has no venereal disease of the vulva or vagina. The anus is much inflamed, red, and swollen. The funnel shape is not marked. There are four shallow ulcers around its border, and a profuse, thick, greenish pus exudes from the parts. She says that she noticed the discharge before the ulcers. The rectum is hot and tender to the touch and more or less filled with the greenish pus, which follows the finger as it is withdrawn. The pus cells contain gonococci in abundance.

The ulcers were washed with the boric-acid solution and touched with a ten-per-cent. solution of nitrate of silver. After irrigating the rectum with the boric-acid solution the ulcers were dressed with pledgets of lint dusted with a powder of equal parts of oxide of zinc and calomel.

The discharge had ceased and the ulcers were granulating satisfactorily when, at the end of two weeks, she disappeared.

These cases are not unique, but they are interesting on account of the few which have been reported as verified by the examination for gonococci.

35 WEST FORTY-FIFTH STREET.

## SOME OBSERVATIONS UPON THE RIVIERA.

By FREDERICK PETERSON, M. D.

In the issue of the *Journal* for June 13, 1891, I published some notes upon Southern Health Resorts in the United States, the result of travels and investigations made during the late winter months of last year. Having just spent some two months along the Riviera, which is the chief winter sanatorium of Europe, I have thought some words upon this subject might not prove uninteresting to such of

your readers as have not visited this favored locality, and who are not in a position like myself to draw contrasts between these foreign health resorts and our own.

The Riviera, as is well known, is the region upon the Mediterranean coast extending from Toulon in France to Leghorn in Italy. It is sometimes divided into the Western and Eastern Riviera, the former, the more important, comprising the district between Toulon and San Remo; the latter, that between San Remo and Leghorn. The chief invalid stations are, in their order from west to east, Hyères with Costebelle, St. Raphael, Cannes, Nice, Mentone (French), San Remo (Italian). All of these places are upon the tideless Midland Sea and nearly at sea-level. Back of them are lofty mountains, some of them snow-capped, the Maritime Alps, which give the coast a rugged and magnificent aspect. Immediately behind Hyères are the Maures Mountains of moderate height, separating this place from the Alps to the northeast. The great Rhône valley, beginning in Switzerland, sweeps southward through France to the sea immediately west of Marseilles, and therefore west of the Riviera. We now have some of the elements that go to make up the climate of the Littoral. The ordinary moisture of the atmosphere at sea-level is abstracted by the mountains, so that its relative humidity is small. The prevailing winds must either come from the mountains or the sea or be a hybrid from both. A purely south wind, which is not common, would come from the Sahara across the long stretch of warm water, and would be quite warm and dry. It is the *sirocco*. A purely north wind must sweep directly down over snowy mountains and cold valleys. It is cold and piercing and is called the *mistral*. When a great depth of atmosphere is not included, it does not come over the mountains, but, sweeping down the great valley of the Rhône, breaks over to the Riviera from the northwest or west with almost equal intensity and rigor. A direct *mistral* is not frequent. It blows perhaps twelve days in the season. But it would seem to be very common as an indirect assailant. It is seldom that winds of some kind do not blow, for here are some figures of M. Teyssie's for a year in Nice: 88 days more or less strong winds, 257 days mild winds, 21 days of absolute calm. To judge by my own experience in the early months of the winter season, all of the winds have that penetrating, "nipping and eager" character which leads one to the shelter of a wall or hedge if he intends to sit still. In walking they are not unpleasant. I had no experience of warm southerly winds. Rainfalls and cloudiness are comparatively rare. For instance, taking the average in twenty years, the following figures are given for Nice (which are applicable to the other stations also) during the six months' winter season: Clear days, 102; cloudy days, 41; rainy days, 36.

Dr. Cornack, of Hyères, called my attention to the fact that rain there in at least one third of the cases falls at night, and this I corroborated during my stay. The porous soil rapidly absorbs it, and the next day is clear, sunny, and dry under foot as usual.

As to temperature, perhaps more can be understood practically by examination of the flora than by reference to the dry statistics. Although the Riviera lies in about lati-

tude 43° to 44°, corresponding to that of Saratoga and Portland, yet here the oranges are ripening through the winter, and the gardens are all abloom with roses, violets, jonquils, mimosa, jasmine, and other flowers. From the olive forests the crops are gathered in December. The roads and streets are lined with the eucalyptus and palm. The Japanese medlars, the yuccas, the agaves, the aloes, the cacti, and the cork oak flourish luxuriantly. The climate is therefore semi-tropical, and yet you may stand in the midst of this vegetation and shiver with cold. The sun is hot, sometimes unendurable. But in the shade a chill strikes you to the marrow. As soon as the sun sets, on with the overcoat! Entering an unshaded room is like a visit to the catacombs.

But climate is never quite enough for invalids. More important still are the creature comforts. Thanks, not to French or Italian enterprise, but to English and American requirements, these places are all supplied with good water, good sewer systems, and hotels and villas providing every comfort. The plumbing is mostly of London installation. All rooms may be well heated with good wood fires, the fireplaces and fuel being quite adequate, which is not true of many other continental regions. Of course, in the old parts of these towns, with their rambling, narrow, gloomy, foul-smelling streets, the proverbial uncleanness of the Italian and French people prevails, the pavements serving the two purposes of sidewalk and common sewer. Providence protects them from disease and the rain acts as scavenger. Strangers, however, reside far from the older portions of the cities, and only go there when the love of the picturesque gets the better of their sanatory judgment. The old towns must be unhealthful in summer. There are marshes about Hyères and St. Raphael which are said to be malarial in summer. Every town has its parks or botanical and zoological gardens, its open-air concerts, its libraries and reading rooms, its casinos for concerts, theatricals, balls, and the like, magnificent macadamized roads in every direction for drives, beautiful wood and mountain paths for walks, and baths of some sort, it being naturally considered a part of the duty of a health resort to provide more than the climate to make a place attractive and draw money into the pockets of its inhabitants. The mind must have its amusements or occupations while the body is recovering its health.

Much has been written concerning differences of climate between the towns of the Riviera, and very fine distinctions have been drawn which really have no existence. They are all much alike. They have the same semi-tropical flora, the same sea before them, the same mountains behind them. When the *mistral* blows they feel it about alike, for in each town certain hillsides protect at one time and not at another. They are all equally warm, equally dry, equally sunny, equally tonic, equally stimulating.

From what has been written above, it may be understood that the Riviera has a delightful winter climate for all healthy people and for some sick people. But it is a climate not to be recommended without due care and many precautions to delicate invalids. Quite recently Dr. Thomas Linn, an American physician, practicing in Nice, has printed in a little book some excellent rules to be observed by Riviera patients, some of which I can not for-

bear to repeat here, since they have their application also to some of our own American climates. They are as follows:

"Do not travel South too quickly.

"Do not put off coming South until too late in the year.

"Do not hurry away from the South too soon in the spring.

"The regimen must be changed in the South.

"See that the sanitary arrangements are good in the house.

"Insist on having a room facing the south.

"All invalids should go indoors before the sun sets and not go out before it rises.

"When going from the sun into the shade, put on additional covering.

"It is necessary to carry a sun umbrella.

"It is advisable to wear smoked eye-glasses in the bright sunshine.

"One should not overdress or walk too fast.

"On entering the house, do not remove outer wraps at once."

The Riviera climate, being the driest in Europe, is a good place for rheumatism and rheumatic neuralgias and for bronchitis and consumption in its early stages. Being stimulating, it is a good place for apathetic forms of mental trouble, like mild melancholia, and for certain forms of neurasthenia, but insomnia is always a contra-indication. Hyères is the best station on the Riviera for several reasons. It has mountain walks and paths through forests of cork oak in greater number than any of the other places can boast. The town is so small that one is practically in the country, whereas in a place like Nice (with nearly 80,000 inhabitants) it is difficult to get out of the city. If one does not sleep well in Hyères, he can go to Costebelle, which is several hundred feet higher and only a mile away. Hyères is three miles from the sea and has, perhaps, more days of absolute calm than the other littoral towns. Hyères is the nearest winter station to Marseilles, and hence is the most accessible from London or Paris, while one may make one's escape from the Riviera at this point in very short order by rail or boat should the climate prove to be hurtful in any degree. In a few hours one may be sailing from Marseilles to Malaga, Oran, Tangier, the Canary Islands, Algiers, or Egypt in search of more suitable winter climes.

Now, when we seek in America some homologous climate we meet with difficulties. We have certainly nowhere just the same juxtaposition of lofty mountain and warm sea. We may discover a similar flora in parts of Florida and in southern California; the dryness in Aiken, Thomasville, and Colorado; the equable temperature and cloudless skies in many places; but the exact combination of isotherms and isobars is not to be found.

I do not think any good climatologist would say so, but I have heard Colorado Springs, Asheville, and Aiken each spoken of as the "Hyères of America." For my part, I have no doubt that in Colorado and New Mexico we have climates which, if not comparable to that of the Riviera, are not so because they are so much better. As for Asheville, it is not exactly a winter resort, though an excellent health station for the nine months of the year preceding January 1st. We have yet to learn authoritatively

whether it is a particularly dry climate. The Riviera resorts are mostly about at sea level and littoral, Asheville being several hundred miles inland at an elevation of 2,400 feet. The contrast of the semi-tropical flora of the Riviera with the seasonally varying northern flora of Asheville is still more pronounced. Aiken has neither mountain nor sea, but depends for its dryness upon its miles of piny sand-hills. Its flora, too, is northern.

The climate of southern California is, perhaps, the nearest akin to that of the Riviera. It is akin to it, but is better. It has not the night and day temperature variations of the Littoral. It is quite as sunny and clear. It is, perhaps, warmer. It may not be so dry. The flora is quite the same. The mountain panorama is not so beautiful, and the villas and villages are not so picturesque. It is not so dangerous and treacherous, for it has no mistral to pounce upon and make easy prey of unsuspecting victims. It does not stimulate you to walk fast or pour the poison of its subtle chills through your pores when you stop to rest a moment. In California, in New Mexico, in Aiken, and in Thomasville we have far better climates than can be found in the south of France, and it seems to me a grievous wrong that American invalids should be sent, as they seem to be in considerable numbers, so far from home when better climatological remedies lie so near at hand.

The Riviera certainly has been, and is still, the great resort for consumptives from all parts of Europe, and is full of Russians, Germans, Swedes, British, and the like; but Teneriffe, Algiers, and Egypt are beginning to deflect from it large portions of that annual tide of phthisical hibernants. So, too, many go to the higher Alpine stations for that "cold" treatment that has come into vogue of late years and which, it seems to me, we Americans misapply when we try to substitute Minnesota and the Adirondacks for the rare, cold atmosphere of high altitudes in southern countries like Switzerland. It is not yet fashionable in Europe to send consumptives to Norway or Siberia for the winter.

When one sees how much is done for the entertainment of visitors and invalids in these European resorts, one can not but regret that lack of local enterprise in America which blinds the tax-payers and voters to their own advantages. How much might they not do to increase the value of their town property to attract visitors, to stimulate the trade of the community, if they would but see the indices before their eyes!

Suppose that Asheville should pave all her streets, should macadamize her country roads for several miles from town, should construct paths along her picturesque mountains, should lay out a public park with swimming baths by the French Broad, should establish a botanical and zoological garden, should line her avenues with rare trees, should build a casino with restaurant, parlors, reading-rooms, library, solarium, concert-hall, theatre—but the imagination halts at the metamorphosis. She might make herself the most beautiful, the most charming, the most attractive (and the best-paying) health resort in the United States. She could defy bad winters and make herself happy and enjoyable all the year round.

THE  
NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, APRIL 2, 1892.

THE TREATMENT OF ENDOMETRITIS.

AT a recent meeting of the Philadelphia County Medical Society a paper was read in which the author advocated the use of intra-uterine injections for the cure of chronic endometritis. In the discussion that followed, Dr. Charles P. Noble made some remarks that seem to us most judicious.

A mere discharge from the uterus, he said, did not indicate endometritis. We were indebted to Dr. Emmet and others for disproving the idea that every uterine discharge indicated endometritis. This might come from various constitutional derangements, such as a feeble heart, general debility, phthisis, constipation, or a sluggish portal circulation, and if these were remedied the discharge would disappear. This class of cases must be eliminated strictly when discussing endometritis. Some even went so far as to deny that there was such a disease as endometritis. The speaker had not studied the endometrium microscopically, but clinically he believed that there was such a thing as endometritis. Another important point in the study of endometritis from the therapeutic standpoint was whether the disease was or was not complicated. Treatment that was beneficial in uncomplicated endometritis might be and was dangerous where complications existed. Endometritis was often the forerunner of salpingitis, which was the forerunner of peritonitis. Patients with chronic peritonitis generally had endometritis. It was apparent that the treatment of such cases should be essentially different from the treatment of uncomplicated endometritis. Where the endometritis was uncomplicated, treatment directed to the uterus was moderately safe, although even here one might produce complications from intra-uterine applications, and especially from intra-uterine injections. The experience of our predecessors had proved this, and had shown that most cases of endometritis could be cured without treating the endometrium directly. When the cervix was dilated widely, as after curetting, the danger of intra-uterine injections was probably slight; but without such dilatation they were distinctly dangerous—how much so any old book on gynecology would prove.

THE BROOKLYN METHODIST EPISCOPAL HOSPITAL.

This institution—better known as the Seney Hospital, from the name of its founder, Mr. George I. Seney—has been open for patients but little more than four years. The *Fourth Annual Report*, for the year ending October 31, 1891, shows clearly that in this short time it has done a noteworthy amount of good work, not only in its primary sphere of relieving the sick, but also in contributing to the advancement of the medical art,

in training young physicians and surgeons, and in fitting young women to act as efficient nurses.

The *Report* is an octavo of nearly a hundred and fifty pages, and the greater portion of it is taken up with statistical accounts of the work done in the medical and surgical divisions, interwoven with brief but unusually well prepared outlines of the clinical histories of interesting cases. This is a feature that we should be glad to see in the annual reports of more of our large hospitals. The fundamental object of hospitals, of course, is to shelter the sick and injured and to afford them the best attainable treatment of their ailments, but it is not only legitimate, but positively desirable, for them to devote a considerable part of their resources, even if they are not ample, to publications of this sort, for they serve far better than mere tables of figures to spread among the medical profession and, through its members, among the community a realizing sense of what the institutions are really accomplishing and of the degree in which they are respectively worthy of additional benefactions. Moreover, by such a course the members of the medical staff are encouraged to strive harder than ever for continuous improvement in their work, and men of the best attainments are led to seek the office of physician or surgeon.

The plan of teaching given the pupil nurses is outlined in the *Report*, and we must say of it that it seems excellent.

MINOR PARAGRAPHS.

THE EFFECT OF LEAD POISONING UPON THE PERISTALTIC ACTION OF THE INTESTINES.

PROFESSOR BOKAI, of Budapest, during a series of experimental studies regarding the pathology of the peristaltic action of the intestines, produced lead poisoning in a number of rabbits by the administration of from one to five cubic centimetres of sugar of lead for from five to forty-six days, and the *Deutsche Medicinal-Zeitung* furnishes us with a brief *résumé* of the results. The positive results were that he found the intestines deficient in blood, the mucous membrane dry, and the large intestine filled with numerous dry balls of fæces which could with difficulty be moved onward. The intestines were highly hyperæsthetic and hyperalgesic, and the peripheral motor intestinal nerves were in excellent nutritive condition. The negative results were that the reaction of the intestinal muscles showed no change, the nervous system about the intestines showed no special condition of irritation, intestinal movements were not inhibited by section of the vagi, and there appeared no special condition of irritation of the central nervous system. These results lead Bokai to conclude that the obstipation of lead poisoning is due to the dryness of the mucous membrane and of the fæces rather than to paresis or spasm of the intestine or irritation of the splanchnic nerve. The diarrhœa which sometimes occurs is due to the irritation produced by the scybala. He is also inclined to consider attacks of lead colic to be usually of a reflex nature, for he has found that they occur pretty frequently after errors of diet, mechanical irritation, or the administration of laxatives. The spasm of the abdominal muscles during an attack of colic also seems to be of reflex origin. The tension, hardness, and slowness of the pulse he ascribes to the irritation of the vaso-motor nervous system by the chronic lead poisoning, and its elasticity during an attack of colic to a reflex contraction of the blood-vessels.

**THE EXAMINATION OF THE EYES SEPARATELY FOR COLOR-BLINDNESS.**

MR. SNELL calls attention in the *British Medical Journal* to the importance of testing each eye separately for color-blindness. He details a case which came under his observation in which there was green color-blindness of the left eye alone, and a second in which there was red blindness in the right eye and incomplete green blindness in the left. With both eyes open both patients correctly sorted Holmgren's wools, and would probably have passed an ordinary examination for color-blindness. The importance of sufficient examination of every person who may occupy a position where good color vision is requisite can not be too firmly insisted on, and every means should be employed to make such examination perfect. Such a condition is probably rare, for Fontenay, in the *Archives of Ophthalmology*, in 1881, states that he examined two hundred and seventeen persons, and found the two eyes in each case always alike. But this is insufficient to prove that such cases as those here mentioned exist, in which the exclusion of the use of one eye, even for a brief period, might be attended with the possibility of disastrous results.

**THE NON-MEDICAL USES OF POISONOUS DRUGS.**

THE *Pharmaceutical Record* states that enormous quantities of strychnine are used in the Western States for non-medical purposes. The county commissioners of Spokane, Washington, recently made a purchase of 1,500 ounces without entering into competition. The favored drug house gets the contract at a high figure, while the rest of the drug trade is left with huge stocks of the drug—enough to last many generations, according to ordinary demands. The mystery seems to be that there should be a public demand on the part of a county of not more than 25,000 population for so large an amount of poison, when a single ounce of it will last most drug stores many months, if not years. The non-medical sale of poisons in the West is very great, and it is believed that most of the strychnine produced, for example, is consumed in the work of destroying animal life. To kill game and destructive animals, such as wolves, foxes, squirrels, rabbits, etc., the farmer and the hunter find the poisonous drugs useful, whether they are in pursuit of bounty money or the animals' pelts.

**ETHER AS A STIMULANT.**

THE *Lancet* is the authority for the statement that in a certain English temperance hospital ether is allowed as a stimulant, instead of alcohol. Referring to the ether drinking vice in Ireland, it is truly said that it is "affectation to regard the use of such an agent as morally or physically better than the use of approved forms of alcohol."

**THE PHYSICIANS' MUTUAL AID ASSOCIATION.**

It is announced that the membership of the New York Physicians' Mutual Aid Association now amounts to a thousand, and that when it reaches eleven hundred the association will be able to pay \$1,000 on each death. This sum is the limit fixed by the by laws, and it ought to be reached soon.

**THE FLINT CLUB.**

BALTIMORE has an organization of physicians bearing the title of the Flint Club, named after the late Dr. Austin Flint. The membership numbers over thirty of the most social and clever of the rising generation of doctors. The meetings are

held monthly for the purpose of increasing the members' gas-tronomic knowledge and of forgetting for the time being everything of a medical nature. Feasting and a flow of wit rule the hour one night out of every thirty for the members of this ingenious coterie.

**ITEMS, ETC.**

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending March 29, 1892:

DISEASES.	Week ending Mar. 22.		Week ending Mar. 29.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	2	6	0	0
Typhoid fever.....	9	6	13	5
Scarlet fever.....	215	28	206	22
Cerebro-spinal meningitis....	4	4	4	3
Measles.....	282	23	423	16
Diphtheria.....	109	37	124	34
Small-pox.....	4	1	3	0
Erysipelas.....	2	0	0	0
Varicella.....	10	0	0	0
Pertussis.....	2	3	0	0
Mumps.....	2	0	0	0

**The Association of the Alumni of the New York Hospital.**—At the meeting for organization, to which we referred last week, the following officers were elected: President, Dr. Thomas M. Markoe; vice-president, Dr. William Gilman Thompson; secretary, Dr. Edwin T. Doubleday; treasurer, Dr. Henry A. Griffin; executive committee, Dr. Frank P. Foster, Dr. George R. Lockwood, and Dr. C. R. Garrison; committee on entertainment, Dr. John L. Adams, Dr. Paul Kimball, and Dr. Percy Bolton; committee on admissions, Dr. C. S. Cole, Dr. W. F. Martin, and Dr. George H. Cobb. Meetings are to be held on the second Friday of February, April, October, and December.

**To Deodorize Iodoform.**—The following combination is allowed by the Addendum of the *Netherland Pharmacopœia* to deodorize iodoform: Carbolic acid, one part; oil of peppermint, two parts; iodoform, one hundred and ninety-seven parts.

**Meetings of State Medical Societies for the Month of April.**—Florida Medical Association, Key West, 5th; Medical Society of the State of Tennessee, Knoxville, 12th; Medical Society of the State of California, San Francisco, 19th; Medical Association of Montana, Butte, 20th; Mississippi State Medical Association, Natchez, 20th; Medical and Surgical Faculty of Maryland, Baltimore, 26th; Texas State Medical Association, Tyler, 26th; Louisiana State Medical Society, New Orleans, 27th; South Carolina Medical Association, Georgetown, 28th.

**The Brooklyn Dermatological and Genito-urinary Society** has been organized with Dr. Samuel Sherwell as president, Dr. A. E. Smylie as vice-president, and Dr. George D. Holsten as secretary and treasurer. The meetings, which are private, are held on the first Friday of each month, except July, August, and September.

**Changes of Address.**—Dr. Birdette P. Craig, to No. 258 Montgomery Street, Jersey City; Dr. J. M. Hays, to No. 826 Fourteenth Street, N. W., Washington; Dr. M. J. Roberts, to No. 122 West Seventy-first Street.

**The Doctor's Retort.**—The *Evening Post* quotes the following from the *Leviston Journal*: One of the brightest physicians of Portland and one of the ablest theologians of Bath were in the physiological room at Bowdoin Medical School, not long ago, examining, in company with others, microscopic slides, showing certain peculiar glands of the intestines. The physician at once launched out into a brilliant discussion of the glands and their relation to various diseases. The theologian grew tired after a time, and finally said: "You doctors know so much about the uncertainties of this world that I should think you would not want to live." "You theologians," came the quick reply, "tell us so much about the certainties of the next that we don't want to die."

**The New York Otological Society** has recently been organized. The meetings are held upon the third Tuesday of November, January, March, and May. The work of organization was completed at a meeting held on March 22d, at the house of Dr. Gorham Bacon, at which time the following officers were elected: President, Dr. Albert H. Buek; vice-president, Dr. Emil Gruening; secretary, Dr. E. B. Dench. The first regular meeting will be held on Tuesday, May 17th, at 8 P. M.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 13 to March 26, 1892:*

TOWN, FRANCIS L., Lieutenant-Colonel and Surgeon, while on duty at Headquarters, Department of California, in charge of the office of the Medical Director, will, in addition to said duty, examine recruits at the rendezvous in San Francisco, Cal.

DE WITT, THEODORE F., First Lieutenant and Assistant Surgeon, is granted leave of absence to include May 16, 1892, at which date his resignation has been accepted by the President to take effect.

JOHNSON, R. W., Captain and Assistant Surgeon. The leave of absence granted for seven days is hereby extended fourteen days.

MUNDAY, BENJAMIN, Captain and Assistant Surgeon, is granted leave of absence for one month, with permission to apply for an extension of one month.

#### Promotions.

BAILY, JOSEPH C., Lieutenant-Colonel and Assistant Medical Purveyor, to be Surgeon, with the rank of Colonel, March 9, 1892, *vice* Norris, retired from active service.

WOLVERTON, WILLIAM D., Major and Surgeon, to be Assistant Medical Purveyor, with the rank of Lieutenant-Colonel, March 9, 1892, *vice* Baily, promoted.

SKINNER, JOHN O., Captain and Assistant Surgeon, to be Surgeon, with the rank of Major, March 9, 1892, *vice* Wolverton, promoted.

#### Appointments.

WINTER, FRANCIS A., of Alabama, to be Assistant Surgeon, with the rank of First Lieutenant, March 9, 1892, *vice* De Hanne, retired from active service.

PURVIANCE, WILLIAM E., of Illinois, to be Assistant Surgeon, with the rank of First Lieutenant, March 9, 1892, *vice* Steimmetz, retired from active service.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending March 26, 1892:*

HOELLING, A. A., Medical Inspector. Ordered as President Naval Medical Examining Board.

NEILSON, J. L., Surgeon. Ordered as member and Recorder of Naval Medical Examining Board.

WALTON, T. C., Medical Inspector. Granted six months' extension of leave, with permission to remain abroad.

BAGG, CHARLES PERRY, of Los Angeles, California, commissioned an Assistant Surgeon in the Navy.

#### Society Meetings for the Coming Week:

MONDAY, *April 4th*: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica Medical Library Association; Coming, N. Y., Academy of Medicine; Boston Society for Medical Observation; St. Albans, Vt., Medical Association (annual); Providence, R. I., Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society (annual).

TUESDAY, *April 5th*: Florida Medical Association (first day—Key West); New York Obstetrical Society (private); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Buffalo Medical and Surgical Association (private); Ogdensburgh, N. Y., Medical Association; Medical Societies of the Counties of Broome (quarterly) and Niagara (quarterly—Lockport), N. Y.; Hudson, N. J., County Medical Society (Jersey City); Essex, N. J. (annual—Newark) and Union, N. J. (annual—Elizabeth), County Medical Societies; Androscoggin, Me., County Medical Association (Lewiston); Chittenden, Vt., County Medical Society; Baltimore Academy of Medicine.

WEDNESDAY, *April 6th*: Florida Medical Association (second day); Society of the Alumni of Bellevue Hospital; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton), N. Y.; Bridgeport, Conn., Medical Association; Penobscot, Me., County Medical Society (Bangor); Philadelphia County Medical Society.

THURSDAY, *April 7th*: New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, N. Y.; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington); Washington, Vt., County Medical Society.

FRIDAY, *April 8th*: New York Academy of Medicine (Section in Neurology); Yorkville Medical Association (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties, N. Y.

SATURDAY, *April 9th*: Obstetrical Society of Boston (private).

#### Answers to Correspondents:

No. 377.—An examination has to be passed. For particulars you had better write to the Board of Regents of the University of the State of New York, Albany.

No. 378.—The organs removed were undoubtedly subject to the husband's disposition.

## Letters to the Editor.

### AN IMPOSTOR.

56 EAST TWENTY-FIFTH STREET, NEW YORK, *March 25, 1892.*

*To the Editor of the New York Medical Journal:*

SIR: Some months ago a person calling himself Dr. Goodman, and pretending to have been my schoolmate, friend, and benefactor, succeeded in extracting various sums of money from a number of professional men in several Western cities. His method was to sell a gas-burner of his invention, but never to deliver it. Dr. F. M. Bauer, of 225 East Eighty-sixth Street, has informed me, in a letter dated yesterday, that a Dr. Goodman tried the same game on him. I beg to notify the members of the profession to be on their guard against this person, whom I do not know, and who apparently is a common swindler. Have him arrested.

ARPAD G. GERSTER, M. D.

## Proceedings of Societies.

### NEW YORK ACADEMY OF MEDICINE.

*Meeting of March 3, 1892.*

The President, Dr. ALFRED L. LOOMIS, in the Chair.

**Cases of Appendicitis illustrating Different Forms of the Disease, with Remarks.**—Dr. CHARLES MCBURNEY read a paper with this title. He urged the importance of opening the peritoneal cavity in cases in which this condition existed, differing in this respect with Treves, who was in favor of avoiding such a procedure. There were cases, however, in which it was preferable to avoid the danger of a peritoneal incision if it was at all probable that the abscess would approach the surface, especially in very fat persons, in the very old, and in the very young. Cases were narrated illustrating the various complications that might accompany the disease. The author did not believe that the temperature was a safe guide in determining the severity of the disease. Thus it was not infrequently the

case that the temperature would fall from 101° to 98° F., and a recurrence of bad symptoms would indicate that an operation was required. An incision having been made, it was not always possible to see the diseased structures: the fingers would often discover the lesion when the eyes did not. If the adhesions were very firm, they should be cut; those which were less firm could be torn. A gangrenous condition of the tissues developed early in some cases, and this fact emphasized the necessity of early operations. In other words, a diagnosis having been made early in the history of the disease, an operation must be done early to insure success. Of fifty cases in which the operation had been one of election, only one had resulted fatally. Some writers had asserted the reliability of examination through the rectum. This method was not approved of by the author. It was not desirable to wait until perforation through the rectum was imminent. Recurrent or relapsing appendicitis in patients who had not been operated upon were of frequent occurrence, one attack being frequently followed by others, and each being more dangerous than the previous one, besides involving loss of time, etc. Moreover, the recurrences might take place at a time when surgical relief was not available. Operations in recurrent attacks were likely to be much more difficult, and therefore more dangerous, than under the primary conditions of the disease. It was not deemed advisable to operate while the patient was suffering from shock, as in cases in which perforation had occurred. It was well to wait until the patient had rallied, and then perform the operation as quickly as possible. The author believed that the operation had established itself as a reliable and justifiable procedure, and that it had been so established more quickly than was usual with operations of equal magnitude.

Dr. FRANCIS DELAFIELD defined the province of the physician in the condition under discussion as that of making the diagnosis and saying what should be done, while the surgeon was to act upon the physician's recommendation. The responsibility of the one differed from that of the other, and he believed that there might be an honest difference of opinion between the two attendants. He thought it probable that in some of the cases that had been narrated permanent recovery would have occurred if an operation had not been performed, but in these doubtful cases he admitted that it was very difficult to decide as to the proper course to pursue. It must also be admitted that after an operation the abdominal wall was weakened on account of the presence of cicatricial tissue. If gangrene of the appendix was present, a fatal issue was inevitable, unless an operation was performed. In such cases general sepsis occurred very quickly, the phenomena resembling those of malignant diphtheria. In recurrent appendicitis the diagnosis was very difficult, and the question as to the propriety of operating could not be easily decided. He believed that many cases in which the diagnosis was that of recurrent appendicitis were not appendicitis at all. If there was perforation, an immediate operation was imperative, but in some cases he believed that the area of perforation was quickly shut in by adhesions.

Dr. LEWIS A. SRIMSON referred in a complimentary manner to the services of the author of the paper in increasing our knowledge of the subject of appendicitis, and congratulated him on the excellent results that had attended his efforts. He thought there should be no question as to the propriety of operating in cases of appendicitis, in view of the serious character of the condition. There was still misunderstanding as to the scope of the remedy which was proposed. The risks of the operation had been alluded to; the risks of the disease should also be seriously appreciated. The patients that died without operation were not reported. Again, the merits of the operation were too often judged by cases in which it had been delayed until

general peritonitis occurred. In cases in which a cure was supposed to be effected by medical treatment there was usually only a temporary cessation of the condition. The only way to be sure of the existing condition was to make an incision and find out by examination.

Dr. A. JACOBI was not sure that a diagnosis in doubtful cases should always be made by means of the cutting operation. It was possible to make a diagnosis by other means. The anatomical lesions causing the symptoms of appendicitis might be various and might not always require an operation. There were at least three conditions which presented similar symptoms—namely, perityphlitis, paratyphlitis, and appendicitis. If all the customary symptoms were present with the exception of swelling, an operation would be indicated. If swelling was present at the outset of the disease, he would be inclined to wait before advising an operation. In paratyphlitis the abscess was entirely outside the peritonæum, and the appendix was not involved. He had seen many cases of that character in which recovery had occurred without an operation. The disease would also differ with the age of the patient. In infants and children the appendix was very large, and appendicitis was of common occurrence. In the aged the appendix was small, and hence with them appendicitis was relatively infrequent. Sonnenburg, of Berlin, had advised operating very early in the history of the disease, the tissues being divided only as far as the peritonæum, and a secondary operation being performed if the condition required it. For doubtful cases it seemed to the speaker that such a course was advisable.

Dr. F. P. KINNICUTT had seen thirteen cases of the disease in the past twelve months, and some of them he had studied from their very inception. Of these cases, resolution had taken place in three without an operation, and in nine cases operations had been performed. In nine of the cases there had been recurrent attacks, and he had reached the conclusion that in catarrhal appendicitis recurrences were frequent and probable. For such cases medical treatment was unavailing. If perforation occurred, there was usually severe pain with vomiting. There might be a remission of the bad symptoms for twenty-four hours, followed by recurrence. The treatment of such cases with laxatives was deemed unavailing and unwise; opium might be given for the relief of the pain.

Dr. ROBERT ABBE believed that appendicitis began as a catarrhal inflammation, and that gangrene was not the first manifestation, though it might occur very quickly in the history of the disease. He believed that the condition was identical in children and in adults. It had been stated by some writers that suppuration did not occur in the recurrent conditions, but clinical investigation did not sustain such a statement. He believed that suppuration and a fatal issue might occur in such cases. The gravest responsibility rested with the physician, who frequently delayed in calling the surgeon to his assistance until the disease was too far advanced to be curable. A period of quiescence might begin on the second day of the disease, when the inflammatory mass had been shut in by plastic lymph. Subsequently this barrier was broken down and the severe symptoms recurred, possibly with a fatal result. In some of the cases in which the speaker had operated he had found it advantageous to make counter-openings in the loins, thus obtaining thorough drainage. He concurred in the statement that purgation was not to be recommended in this disease.

Dr. A. G. GERSTER thought it was now admitted by physicians that early operations in appendicitis were or might be necessary. He concurred in the statement that those cases in which swelling was prominent in the early history of the disease were not necessarily the ones to be operated upon. He saw no reason why a diagnosis should not be made by means of an ex-

ploratory incision, just as it was made in other diseased conditions. Like the author of the paper, he objected to operating while the patient was in shock; it was better to wait until the symptoms had improved. It was true that hernia was a possible sequel to an operation, but such an accident could usually be obviated if special care was exercised. The operation should not be performed by one who was without skill or experience in this line of work. The incision might be made in the median line, and if this did not enable one to reach the abscess, a second incision might be made in the loin.

Dr. W. H. DRAPER thought that the physician should have the responsibility and direction of cases of appendicitis, the surgeon being subject to his guidance. He appreciated the statement that it was often very difficult to diagnosticate appendicitis, and there were several conditions which might be confounded with it. Among such conditions might be mentioned salpingitis, oophoritis, and stricture of one or another portion of the intestine. He admitted the value of exploratory incisions for this disease, and believed that patients who recovered without an operation were very likely to be subject to recurrence.

The PRESIDENT believed that patients might recover from this disease without an operation and be free from recurrence. This had been shown by post-mortem statistics. Clinically, one should recognize mild cases and severe cases, and much was to be learned in this particular from the aspect of the patient. He believed that the first attack of the disease was usually mild; subsequent ones might be more severe. With the first appearance of sepsis or shock the assistance of the surgeon should be sought. In general, he would say that if improvement were not apparent within forty-eight hours from the inception of the disease, consultation with a surgeon should be sought. Medical treatment was not usually efficient in secondary attacks. As long as induration in the diseased area was present there was a condition of danger. If there was doubt as to the existing condition of affairs an exploratory incision was indicated.

Dr. McBURNEY admitted the possibility of hernia as a sequel to an operation for appendicitis, but he thought that improved methods of operating would overcome this objection. As to the method of operating at two different periods, it was neither new nor would it be generally useful. It had been practiced years ago by the late Dr. Sands, and there were many cases in which the abscess was too deeply seated to be influenced by an incision which extended only to the peritonæum.

#### SECTION IN ORTHOPÆDIC SURGERY.

*Meeting of February 19, 1892.*

Dr. HENRY LING TAYLOR in the Chair.

#### Rotary Lateral Curvature of the Spine after Empyema and Poliomyelitis.—

Dr. W. R. TOWNSEND presented a girl, fourteen years of age, with rotary lateral curvature of the spine. At the age of three years, and after whooping-cough, she had had an empyema on the left side, which had opened spontaneously. The sinuses had continued to discharge for five years, and the three cicatrices—one to the left of the nipple and two slightly below and to the right—showed the points where the openings had occurred. When she was five years old, it had been noticed one morning that there was a complete loss of power in the left upper extremity. The mother said there had never been any curvature of the spine before the attack of paralysis, although the child had always slept on the left side, and the curvature had been steadily increasing since then. The circumference of the chest at the nipples was twenty-four inches, the right side measuring fifteen, and the left nine inches. There was a very marked lateral rotary deviation of the spinal column

to the right, extending from the seventh cervical to the tenth dorsal, with compensating curves above and below. There was no torticollis. The breathing space was good, considering the amount of the deformity. The heart was not displaced. There was complete loss of reaction to faradism in the left supraspinatus and infraspinatus and in the deltoid, and a reversal of the formula with the galvanic current. There was no anæsthesia, but marked atrophy of the shoulder and upper left arm. There was a partial loss of reaction in the pectoral, but the biceps, triceps, and forearm muscles reacted well. The interesting feature was the relation of the rotary curvature to the empyema and the poliomyelitis. The speaker's opinion was that the empyema had probably caused a slight curvature, and that the paralysis had helped to increase it, but that there was no connection between the empyema and the paralysis; in other words, the paralysis was not produced by the scoliosis, but was separate and distinct and due to a poliomyelitis. He had presented the case chiefly because it was of interest in connection with the first paper announced for the evening.

Dr. ROYAL WHITMAN also presented a little girl as an illustration of a pure rotary lateral curvature caused by anterior poliomyelitis.

Dr. H. W. BERG said that he had had an opportunity of seeing this patient, and had obtained a somewhat different history. According to this version, the patient was still in bed with the empyema when the family first noticed that she was lying more upon the left side. The occurrence of the paralysis had been sudden, and the attending physician had allowed her to get out of bed, and at this time the extreme lateral curvature had first been noticed. If this curvature was the result of the poliomyelitis, it would not have been so extreme at this early stage, for it took time for muscles to contract and cause deformity. In this case the paralyzed muscles were on the left side of the body and the primary curve toward the right, while in cases of lateral curvature due to paralysis the healthy muscles must necessarily be on the concave side of the deformity. The only way in which poliomyelitis could possibly produce a curvature on the concave side of the deformity would be in the third stage of this disease—*i. e.*, in the third or fourth year after the paralysis, when the muscles began to contract into firm fibrous cords.

Dr. ROYAL WHITMAN thought that, if the long supporting muscles were paralyzed, it might be as the previous speaker had said; but in these cases where only the muscles supplying the shoulder were paralyzed, one would expect the curvature to be toward the opposite side.

Dr. BERG replied that the intrinsic muscles were not alone paralyzed in this case. Lateral curvature must follow contraction of the intrinsic muscles of the spine, and not of the long muscles.

Dr. R. H. SAYRE had seen a number of cases of lateral curvature dependent upon poliomyelitis with paralyzes of the external muscles on the concave side, and hence, he thought, the statement that the convexity was always on the side of the paralyzed muscles could not be accepted without qualification. He had been surprised that German writers took it for granted that empyema curves were not rotary.

Dr. S. KETCHUM was not prepared to indorse the view that the curvature was mainly due to the empyema; on the contrary, he thought the patient had that form of curvature usually found as a result of anterior poliomyelitis. Undoubtedly the empyema tended to exaggerate this curvature.

Dr. N. M. SHAFFER said that, so far as he knew, the first reported case of lateral curvature due to poliomyelitis had been published in his book in 1876 or 1878. That case had been examined by Dr. Seguin, Dr. Draper, and himself, and they had

found the paralysis on the hollow side. On general principles, he believed that Dr. Berg was correct in his statement. In 1881 he had called attention to the fact that a rotary element existed in empyematous curves. It was exceptional for him to find a lateral curvature of the spine, due to empyema, which was not associated with a greater or less degree of rotation. The error probably arose from the fact that Dr. W. J. Little, of London, who had first described it, had made this mistake, and other writers had perpetuated the error.

Dr. MARY PUTNAM JACOBI called attention to the monograph by Eulenberg on lateral curvature of the spine, in which he stated very categorically that in ordinary typical cases of lateral curvature the muscles on the concave side were necessarily the stronger, and explained on this principle the mechanism of the production of lateral curvature. His idea was that it was due to a disturbance in the balance of the muscles of the two sides, whether extrinsic or intrinsic.

Dr. A. B. JUDSON said that in his earlier studies of lateral curvature he had adopted, without due verification, the statement of foreign observers that rotation was absent from the curvature caused by pleural disease. At present he believed that it did not occur, but in a very modified and unimportant degree. The collapse of the chest wall would weaken the action of some of the muscular and fibrous structures which caused rotation by holding the spinous processes nearer the median line than the bodies of the vertebrae. For this reason we might well expect the rotation to be less marked. In the case shown there was little difference in the diagonal diameters, which was the chief feature of rotation, and was caused, in an ordinary case, by the prominence, posteriorly, of the right back of the chest, and the complementary prominence, anteriorly, of the left front of the chest. Here we had prominence before and behind on the right side, and depression before and behind on the left side, with but little difference in the diagonal diameters, a condition very unlike the effect of rotation. Still there might be, and probably was, some rotation in the vertebral column of this patient, although its effect on the deformity was not easily recognizable.

Dr. TOWNSEND said that, owing to the fact that in this case one was compelled to rely wholly upon the varying statements of the parents of the child, who were not very close observers, it would be well to be cautious in drawing conclusions from a study of this case alone. He did not agree with Dr. Berg as to the relation of the paralyzed muscles to the concave side.

**Voluntary Subluxation of the Knee produced by Muscular Action.**—Dr. R. H. SAYRE showed a child of fourteen months presenting this condition. The mother had first noticed this condition when the child was eight months old. When he was excited, the right knee was pushed in and out with a distinct click. The child had been born after a normal labor, and there was no history of injury. The speaker proposed to apply a splint, in order to retain the knee in position.

**An Appliance for the Prevention of Deformity in Hip Disease.**—Dr. WHITMAN presented a case illustrating this appliance. He believed that the long traction brace was the most useful appliance in these cases, for it assured as a perineal crutch a protection which could not be removed by the patient. This was the principal objection to any brace which depended on axillary crutches for its usefulness. Simple fixation of the joint, allowing the patient to walk about on the affected limb, as practiced by Thomas and others, did not afford this protection, which he considered the most important element in the treatment of any joint affection. On the other hand, with the simple long traction brace, gradual and increasing flexion of the leg was a very common and troublesome complication. This was the weak point of the brace, and the one most constantly

attacked by its opponents. He had therefore attempted to combine the merits of two braces as follows: The limb having been brought into perfect position, a slender steel bar, attached above to an encircling thoracic band and terminating just above the knee in a thigh band, was closely applied along the posterior aspect of the joint, after the manner of Thomas. The long traction brace was then applied as usual. Thus flexion was prevented and additional fixation assured, combined with effective protection. By dividing the function of the two braces, the posterior or miniature Thomas brace could be made very light and comfortable; it, however, was not to be used as a lever to correct deformity. This should first be overcome by traction in bed or otherwise. He believed this division of labor to be more practicable than the addition of perineal bands and traction to the ordinary Thomas brace, as suggested by Lovett and De Pass.

Dr. JUDSON commended the use of one apparatus, the hip splint, to protect the joint, and another, the antero-posterior lever, if apparatus was necessary for this purpose, to oppose flexion. In general, it was better not to attempt too many things with one and the same apparatus. He thought the antero-posterior lever, for combating flexion and maintaining fixation, was the essential element of the Thomas splint.

Dr. SNAFFER said that where supplementary apparatus was employed to limit the motion of the dorso-lumbar spine and the motion on the acetabulum, unnecessary traumatism was inflicted upon the acetabulum. He had studied this subject quite closely, and, in his opinion, this motion of the dorso-lumbar spine was one of the greatest aids in the treatment of this condition. It was better to treat flexion by recumbency and rest until the flexion was overcome, than to apply an apparatus which antagonized the very strong action of the flexor muscles.

Dr. WHITMAN said he recognized the force of what Dr. Shaffer had said about the flexibility of the lumbar spine, but he was inclined to think that the motion of the diseased joint which the simple traction brace permitted, and the deformity which it did not prevent, were more important considerations than the theoretical objection which Dr. Shaffer had presented. This fixation apparatus was applied before there was any flexion, and in the case presented there was no spasm of any of the muscles.

#### Does Scoliosis ever give rise to Pressure Myelitis?—

Dr. H. W. BERG read a paper with this title.

Dr. R. H. SAYRE thought there was no doubt that the differences in mammary development observed in cases of rotary lateral curvature were the result of trophic change, but the cause of this disturbance was still uncertain. In advanced cases he had been inclined to attribute this disturbance to pressure on the nerves at their exit from the bony canal. Pathological specimens showed not only a narrowing of the bony canal, but also large exostoses at the points where the vertebrae joined; it was quite possible that these might project inward as well as outward. The case described in the paper had at one time been under his care, and he had considered it as closely resembling disseminated sclerosis, although it was not typical of any diseased condition with which he was familiar. Dr. Spitzka had held the same position. The case had been diagnosed as lateral sclerosis by one neurologist, and as hysteria by another eminent neurologist, who had employed hypnotism upon the patient, though unsuccessfully. She had been referred to the speaker with the idea that there was some pressure on the cord at about the tenth dorsal vertebra, which might possibly be relieved by a surgical operation. He had been unable, however, to detect any mass pressing upon the cord, and, from the effects of momentary suspension, he did not think this method of treatment would prove beneficial. He did not associate the cord lesion with the lateral curvature. The

trophic changes were probably due to disturbance of nutrition external to the cord.

Dr. SHAFFER considered that the author's case of lateral curvature differed only in degree from almost every case of this condition. It was rare to find lateral curvature without an exaggerated tendon reflex, a non-deforming club-foot, or various trophic changes, and the latter occurred in incipient cases, before there could be any pressure on the cord. Girls suffering from lateral curvature were usually peculiarly nervous, and oftentimes seemed to assume the responsibilities of their entire family. This was the direct result of the central nervous lesion—one which pertained more to the psychical condition than to the spinal-cord condition. Our clinical studies drove us by analogy to look in the motor tract of the brain for the cause of the condition.

Dr. KETON looked upon the trophic changes as an element in the ætiology of lateral curvature, rather than the result of this condition. It was probable that, at a very early period in life, there was a disturbance of the nervous system, most probably of the brain, which produced the lateral curvature. Boys having lateral curvature showed atrophy of the limbs, but the general nervousness was not so marked. For example, he had at present under observation a robust boy, fifteen years old, with lateral curvature, who was supernaturally strong and supernaturally slow and apathetic. He thought it highly improbable that pressure myelitis ever occurred in these cases.

Dr. L. W. HUBBARD could not understand how the paraplegia of Pott's disease could be said to be due to cord pressure from change of position, as clinically it seemed to bear no relation to the amount of curvature or the situation of the lesion, and it was present when there was no curvature, and, moreover, recovery took place without any change in the curve of the spine. He saw nothing in the case reported analogous to the myelitis of Pott's disease.

Dr. JUDSON would eliminate muscular contraction as a factor in the causation of lateral curvature, believing that rotation and the curvatures, primary and secondary, were only the mechanical result of muscular failure to sustain the weight of the trunk. He would welcome with extreme pleasure any advance in our exact knowledge of the ætiology of lateral curvature.

Dr. V. P. GIBNEY had never seen pressure myelitis in an uncomplicated case of rotary lateral curvature.

The CHAIRMAN agreed with Dr. Hubbard that the analogy of the case under discussion to the myelitis of Pott's disease was not very strong, as, according to the view advanced by Dr. Hoffa at the last meeting of the American Orthopædic Association, and generally accepted by those present, the paraplegia was due to the pressure of inflammatory products. Personally, he had never seen a case of lateral curvature complicated by paraplegia or symptoms of lateral sclerosis. Last autumn he had had a case of very moderate curvature, with a very peculiar ataxic gait, but a careful examination had excluded organic disease of the spinal cord, and it had been decided to be a case of functional nervous disturbance, possibly produced by masturbation. It seemed strange that such a mild case as the one described in the paper should produce such marked nervous symptoms, while the much more severe cases so often seen had no analogous symptoms. He looked upon the cord lesion as merely a coincidence.

Dr. BERG thought the diagnosis of disseminated sclerosis very improbable, and this diagnosis had probably been made because a primary sclerosis of the cord was such a rare condition that whenever a neurologist saw a spastic paralysis in an adult and could find no cerebral symptoms, or symptoms of pressure upon the cord, he made a diagnosis of disseminated sclerosis. Dr. S. Weir Mitchell had given it as his opinion that the case

was one of primary lateral sclerosis. There was no doubt as to the sclerosis and the lateral curvature; the only doubt was as to the connection between the lateral curvature and the sclerosis. Pott's paraplegia was caused by a variety of conditions, but he believed that in nearly seventy-five per cent. of the cases the paraplegia was due to pressure resulting from flexion of the cord at the angle of the curve. He had no doubt that hundreds of cases had been seen where the lateral curvature had been considered the result of paralysis, where it was really the cause.

**Femoral Abduction, Adduction, and Flexion.**—Dr. JUDSON presented a convenient method of observing the degrees of motion in cured and convalescing cases of hip disease. The subject was illustrated by boards on which dolls were fixed, the center of motion at the hip in each case being surrounded by a graduated arc, with the degrees numbered from zero, in the natural posture of supine recumbency, with a slight lordosis, up to the widest limit of normal motion. In practice the region of motion was first to be found, and then the extent to which it might be pushed, without disturbing the natural and symmetrical position of the lumbar vertebrae and the iliac spines, was to be noted on the goniometer. The degrees of motion in flexion and laterally might thus be readily recorded. The presence of considerable motion warranted a serious effort to reduce whatever deformity might exist. He cited two cases in which the patients, being considered cured, relief had been sought for the deformity. Enough motion had been found to encourage hope, and good results had been recorded in a few months in each case after the application of a hip splint, and, later, a simple ischiadic crutch, and the return of the patient by instruction and drill to the natural rhythm of walking. The improvement had been readily measured in degrees, from time to time, and the deformity had been almost completely reduced.

**A New Method of making Plaster Casts of the Thorax in Cases of Rotary Lateral Curvature.**—Dr. MARY PUTNAM JACOBI exhibited a series of models which she had prepared by an original method. It had been suggested to her by observations made with the cyrtometer upon the condition of the thorax after empyema. An outline of the thorax at the desired level was first taken with a cyrtometer (which was an instrument consisting of two soft strips of lead united by a hinge), which was placed over the vertebral column, and the lead strips closely applied to the chest walls. The lead was next placed upon a slab of marble, where it served as a sort of shallow frame, into which the plaster-of-Paris cream was poured and allowed to set. This gave practically a thin plaster cast, representing a section of the thorax. She called attention to the ease with which the diagonal diameter could be obtained, and also to the way in which these casts brought out small degrees of curvature.

## Book Notices.

*A Treatise on the Ligation of the Great Arteries in Continuity. With Observations on the Nature, Progress, and Treatment of Aneurysm.* By CHARLES A. BALLANCE, M. B., M. S. Lond., F. R. C. S., Assistant Surgeon to St. Thomas's Hospital, etc., and WALTER EDMUNDS, M. A., M. C. Cantab., Resident Medical Officer, St. Thomas's Home. Illustrated by Ten Plates and Two Hundred and Thirty-two Figures. London and New York: Macmillan & Co., 1891. Pp. xxviii to 568. [Price, \$10.]

It is rare that the medical reader is offered a volume so elegantly prepared as this is; but a slight widening of the page

margins, and another quality of paper, and this work, with its delightfully distinct typography, its numerous and excellent illustrations and plates, would be the peer of any *édition de luxe*. It is a pleasure to commend the enterprise of the publishers in these particulars, and the character of the work done by the authors justifies such a presentation of their topic. For seven years Mr. Ballance and Mr. Edmunds have been engaged in the researches on which this volume is founded, and they conclude that in ligation in continuity, in experimental work as well as in human surgery, "the method of rupture leads, with certain arteries, almost inevitably to the dread sequel of hæmorrhage and death; and, further, that the rise of Listerian surgery has not abolished the danger." This last statement will probably be a surprise to some surgeons and will be questioned by others. And yet the various statistics published during the past decade seem to substantiate the statement, and Billroth is quoted as stating that the statistics of hæmorrhage after ligation in continuity probably understate the case.

As a preliminary study of the subject the authors investigated the physiological occlusion of arteries occurring in the circulatory changes at birth and the pathological occlusion that happens in certain diseases. In the former instance they show that Nature does not think it necessary, when occluding the ductus arteriosus, to rupture the inner coats of that vessel, and that it is not divided in order to reduce the longitudinal tension; and yet it is rare that failure to occlude occurs, and hæmorrhage is unknown. So, in pathology, a vessel may be obliterated without either of those supposed necessary features being called into play.

It is demonstrated that the plasma cells of the arterial wall, and not the leucocytes of the blood, form the scar tissue that occludes the artery, and the authors' experiments corroborate Ziegler's to the effect that the connective-tissue corpuscles are the sole active agents in the formation of cicatricial tissue, the leucocyte possessing no fibroblastic power. They found that one of the first results of ligation was a multiplication of the endothelial cells to twice or three times their usual depth; soon the connective-tissue corpuscles in the middle coat became active and subdivided, and the daughter cells of these corpuscles passed through the openings in the membrane of Henle and entered the clot that had formed in the artery. The red corpuscles at the periphery of the clot first lost their sharpness of outline, breaking down into granular masses and becoming oval or fusiform, while those at the center of the clot retained their appearance and shape for a considerable time. Fibrin nodes were formed, about which the invading plasma cells formed islets from which elongated cells were thrown out, uniting with similar processes from other islets. About the fourth week capillaries appeared in the clot, and ultimately the artery became converted into a mere cord of fibrous tissue. This result refutes Bruns's statement that clotting does not take place unless the coats of the artery are ruptured.

They quote from Paré, Monro, Heister, Platner, Bell, John Hunter, and Scarpa to show that these fathers in surgery did not advocate rupture of the internal walls. And to Abernethy they attribute the renaissance of the operation of Celsus, and to Jones the prevalent idea of the necessity of rupturing the internal walls in ligation in continuity.

Their experiments show that the ligature selected should be round, smooth, strong, inelastic, pliable, and not easily absorbed. Even chromated catgut ligatures were easily penetrated by the leucocytes and plasma-cells, the intestinal villi facilitating their entrance into and consequent softening of the ligature. But in kangaroo tendon its homogeneity permitted its absorption from the surface only. Next to kangaroo tendon, ox peritonæum,

boiled floss silk, and silkworm gut proved to be most suitable for ligatures.

In tying the ligature they consider that the reef, granny, or surgical knot may be converted into a slip knot, and they advise a stay knot formed by two or more ligatures tied separately, as in the first half of a reef knot, and then completed by all the ends on each side being tied as in completing a reef knot. The force to be employed in tying the ligature is about the same whatever material is used, and averages about a pound of traction to occlude the vessel without rupture.

In seventy-one experiments on sheep, asses, and horses of ligation of arteries under strict antiseptic precautions they found that the vessels could be permanently occluded without rupture of their coats, and that secondary hæmorrhage did not occur if a suitable ligature was tied in a suitable knot with appropriate force.

The concluding chapter, on the conduct of the operation and the fate of the patient, is one that will prove of interest to all surgeons.

*Surgical Anatomy for Students.* By A. MARMADUKE SHEILD, M. B. (Cantab.), F. R. C. S., Senior Assistant Surgeon, Aural Surgeon, and Teacher of Operative Surgery, Charing Cross Hospital. New York: D. Appleton & Co., 1891.

This little volume is based upon a series of demonstrations that the author has delivered to his students, and, as it is to be used with the living body, it will be found particularly serviceable to students for the purpose of demonstration. The various chapters treat of the different surgical regions of the body, and the practical considerations in each include allusions to the more frequent operations and injuries. It is a compact and satisfactory manual.

#### BOOKS, ETC., RECEIVED.

*The Principles and Practice of Medicine.* Designed for the Use of Practitioners and Students of Medicine. By William Osler, M. D., Fellow of the Royal College of Physicians of London; Professor of Medicine in the Johns Hopkins University and Physician-in-chief to the Johns Hopkins Hospital, Baltimore. New York: D. Appleton & Co., 1892. Pp. xvi to 1079. [Price, \$5.50.]

*A System of Practical Therapeutics.* Edited by Hobart Amory Hare, M. D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Assisted by Walter Chrystie, M. D., formerly Instructor in Physical Diagnosis in the University of Pennsylvania. Vol. II. Fevers—Diseases of the Respiratory System, Circulatory System, and Hæmatopoietic System—Diseases of the Digestive System. With Illustrations. Philadelphia: Lea Brothers & Co., 1892. Pp. 6-17 to 1158.

*A Practical Manual of Diseases of the Skin.* By George H. Rohe, M. D., Professor of Materia Medica, Therapeutics, and Hygiene, and formerly Professor of Dermatology in the College of Physicians and Surgeons, Baltimore. Assisted by J. Williams Lord, A. B., M. D., Lecturer on Dermatology and Bandaging in the College of Physicians and Surgeons, Baltimore. Philadelphia and London: The F. A. Davis Co., 1892. Pp. viii to 303. [No. 13 in the *Physicians' and Students' Ready Reference Series.*]

*The Mediterranean Shores of America.* Southern California: its Climatic, Physical, and Meteorological Conditions. By P. C. Remondino, M. D., Member of the American Medical Association, etc. Fully illustrated. Philadelphia and London: The F. A. Davis Co., 1892. Pp. xiv to 160.

*Abdominal Surgery.* By J. Greig Smith, M. A., F. R. S. E., Surgeon to the Bristol Royal Infirmary; Lecturer on Surgery, Bristol Medical School, etc. Fourth Edition. Philadelphia: P. Blakiston, Son, & Co., 1891. Pp. xviii to 806.

Lectures on Pathology delivered at the London Hospital by the late Henry Gaven Sutton, M. B., F. R. C. P., Physician and Lecturer on Pa-

thology at the London Hospital, etc. Edited by Maurice Eden Paul, M. D., and revised by Samuel Wilks, M. D., LL. D., F. R. S. Philadelphia: P. Blakiston, Son, & Co., 1891. Pp. xviii to 503.

Practical and Analytical Chemistry. A Complete Course in Chemical Analysis. By Henry Trimble, Ph. M., Professor of Analytical Chemistry in the Philadelphia College of Pharmacy. Fourth Edition. With Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1892. Pp. xiii-17 to 119.

The Book of Prescriptions, containing upward of 3,000 Prescriptions collected from the Practice of the most Eminent Physicians and Surgeons, English and Foreign; comprising also a Compendious History of the Materia Medica, Lists of the Doses of all Official or Established Preparations, and an Index of Diseases and Remedies. By Henry Beasley. Seventh Edition. Philadelphia: P. Blakiston, Son, & Co., 1892. Pp. xx to 599.

A Manual of Diseases of the Nervous System. By W. R. Gowers, M. D., F. R. C. P., F. R. S., Consulting Physician to University College Hospital, etc. Second Edition, revised and enlarged. Volume I. Diseases of the Nerves and Spinal Cord. With One Hundred and Eighty Illustrations, including Three Hundred and Seventy Figures. Philadelphia: P. Blakiston, Son, & Co., 1892. Pp. xvi to 616.

A Manual of Autopsies. Designed for the Use of Hospitals for the Insane and other Public Institutions. By I. W. Blackburn, M. D., Pathologist to the Government Hospital for the Insane, Washington, D. C. Illustrated. Philadelphia: P. Blakiston, Son, & Co., 1892. Pp. x-17 to 84.

The Pathology and Prevention of Influenza. By Julius Althaus, M. D., M. R. C. P. Lond., Senior Physician to the Hospital for Epilepsy and Paralysis, Regent's Park. New York: G. P. Putnam's Sons, 1892. Pp. 7 to 64.

Epidemic Influenza: Notes on its Origin and Method of Spread. By Richard Sisley, M. D., Member of the Royal College of Physicians of London. London: Longmans, Green, & Co., 1891. Pp. xi to 150.

Traité clinique et thérapeutique de l'hystérie d'après l'enseignement de la Salpêtrière. Par le Docteur Gilles de la Tourette, ancien chef de clinique des maladies du système nerveux à la Salpêtrière. Préface de M. le Dr. J. M. Charcot, Professeur de clinique des maladies du système nerveux, membre de l'institut. Hystérie normale ou interparoxystique. Avec 46 figures dans le texte. Paris: E. Plon Nourrit et cie., 1891. Pp. xv to 582.

Lehrbuch der Hebammenkunst. Von Dr. Bernhard Sigmund Schultze, Gehcimhofrath öff. ord. Prof. der Geburtshülfe, etc. Zehnte Auflage. Mit 98 Holschnitten. Leipzig: Wilhelm Engelmann, 1891. Pp. xxiii to 380.

Official Transactions of the National Association of Railway Surgeons, 1891.

Transactions of the New Hampshire Medical Society at the Centennial Anniversary, held at Concord, June 15, 16, and 17, 1891.

A Study of the Sputum in Pulmonary Consumption. By E. L. Shurly, M. D., Detroit, Mich. [Reprinted from the *Climatologist*.]

Inaugural Address to the Physiology Class in Anderson's College. Session 1891-'92. By D. Campbell Black, M. D. Glasgow: Hugh Hopkins.

Obstetric Problems: Being an Inquiry into the Nature of the Forces determining Head Presentations, Internal Rotation, and also the Development of the Amnion. By D. T. Smith, M. D., Louisville, Ky. With Illustrations. Louisville: John P. Morton & Co., 1892.

Observation and Experiment in Phthisis. A Reply to Professor Tyndall. By Thomas J. Mays, M. D., Philadelphia. [Reprinted from the *Climatologist*.]

A Study of the Processes which result in the Arrest or Cure of Phthisis. By Henry P. Loomis, M. D., New York. [Reprinted from the *Medical Record*.]

On the Collection of Samples of Water for Bacteriological Analysis. By Wyatt Johnston, M. D., Montreal. [Reprinted from the *Canadian Record of Science*.]

Nomenclature of Diseases to be followed by Physicians in the Indian Service in making Reports to Indian Office. Washington: Government Printing Office, 1892.

A Quarter of a Century's Retrospect of Laryngology. By Lennox

Browne, F. R. C. S. Ed. [Reprinted from the *Journal of Laryngology, Rhinology, and Otology*.]

A Statistical Review of the Proportion and Cause of Blindness in Thirty-two Thousand Eyes consecutively treated in the Jefferson College Hospital. By Howard F. Hansell, M. D., and James H. Bell, M. D., Philadelphia. [Reprinted from the *Archives of Ophthalmology*.]

The Therapeutic Aspect of some Ovarian Disorders. By Edward W. Jenks, M. D., LL. D., Detroit, Mich. [Reprinted from the *Transactions of the American Gynecological Society*.]

The Bicycle in the Treatment of Nervous Diseases. By Græme M. Hammond, M. D., New York. [Reprinted from the *Journal of Nervous and Mental Disease*.]

Seventh Annual Report of the New York Post-graduate Hospital (and the Babies' Wards) for the Year ending September 15, 1891.

Third Annual Report of the Babies' Hospital of the City of New York.

Annual Report of the Board of Managers of the Maryland Hospital for the Insane, November, 1891.

Fourteenth Annual Report of the Presbyterian Eye, Ear, and Throat Charity Hospital, Baltimore.

Additional Report of the Commissioners of Capital Punishment of the State of New York. Transmitted to the Legislature January 19, 1892.

Transactions of the American Association of Obstetricians and Gynecologists. Vol. IV. For the Year 1891. Philadelphia: W. J. Dornan, 1892.

Some Points in the Diagnosis and Nature of Certain Functional and Organic Nervous Diseases. By J. T. Eskridge, M. D., Denver, Colorado. [Reprinted from the *Alienist and Neurologist*.]

Subacute Recurrent Multiple Neuritis. By J. T. Eskridge, M. D., Denver, Colorado. [Reprinted from the *Journal of Nervous and Mental Disease*.]

The Indications for Colotomy. By Charles B. Kelsey, M. D., New York. [Reprinted from the *Therapeutic Gazette*.]

Transactions of the American Surgical Association. Volume the Ninth. Edited by J. Ewing Mears, M. D. Philadelphia: William J. Dornan, 1891.

Transactions of the American Otological Society. Twenty-fourth Annual Meeting. Arlington House, Washington, D. C., September 22, 1891. Vol. V. Part I.

A Text-book of Nursing, for the Use of Training Schools, Families, and Private Students. Compiled by Clara S. Weeks-Shaw. Second Edition, revised and enlarged, with Illustrations. New York: D. Appleton & Co., 1892. Pp. 8-11 to 391. [Price, \$1.75.]

The Pocket Pharmacy, with Therapeutic Index. A *Résumé* of the Clinical Applications of Remedies adapted to the Pocket-case, for the Treatment of Emergencies and Acute Diseases. By John Aulde, M. D., Member of the American Medical Association, of the Medical Society of the State of Pennsylvania, etc. New York: D. Appleton & Co., 1892. Pp. 16-17 to 204. [Price, \$2.]

The Year-book of Treatment for 1892. A Critical Review for Practitioners of Medicine and Surgery. Philadelphia: Lea Brothers & Co., 1892. Pp. vii to 486.

The Miitter Lectures on Surgical Pathology. Delivered before the College of Physicians of Philadelphia, 1890-'91. By Roswell Park, A. M., M. D., Professor of Surgery, Medical Department, University of Buffalo. [Reprinted from the *Annals of Surgery*.]

Traitément des maladies de la peau, avec un abrégé de la symptomatologie, du diagnostic et de l'étiologie des dermatoses. Par le Dr. L. Brocq, Médecin des hôpitaux de Paris. La partie pharmacologique a été revue par M. L. Portes, Pharmacien en chef de l'Hôpital Saint-Louis de Paris. Deuxième édition, corrigée et augmentée. Paris: Octave Doin, 1892. Pp. ix-894. [Prix, 15 francs.]

Traité de médecine. Publié sous la direction de MM. Charcot, Professeur de clinique des maladies nerveuses à la Faculté de médecine de Paris; Bouchard, Professeur de pathologie générale à la Faculté de médecine de Paris, et Brissaud, Professeur agrégé à la Faculté de médecine de Paris. Par MM. Babinski, Ballet, Brault, Chantemesse, Charrin, Chauffard, Gilbert, Guinon, Legendre, Marfan, Marie, Mathieu, Netter, Octinger, André Petit, Richardière, Roger, Ruault, Thibierge,

During 1890 the enteric deaths numbered 1,008; in 1891, 1,997; corresponding to the death-rates of 0.9 and 1.6 respectively. It was pointed out that the general death-rate of Chicago was by no means high, and that the excessive mortality from enteric fever was in ominous accordance with what was known of the danger of pollution of the water supply by sewage. The city stands, as everybody knows, on the shore of Lake Michigan, and takes its water supply from that source. It seems that the sewage of some 180,000 persons passes directly into the lake; and that further pollution is brought about by means of the Chicago River, which communicates with the Mississippi as well as Lake Michigan, and delivers its polluted waters in either direction, according to circumstances. The water intake is at different points in the lake which do not seem to be sufficiently far removed from the sources of pollution to afford any satisfactory assurance of safety. A proposal to construct a water tunnel four miles in length has not yet been carried out.

The statements made as to the prevalence of fever were at first met with flat contradiction. According to the health commissioner for Chicago the assertions were ridiculous; there was not, and had not been, any epidemic; it was simply a scare intended to frighten people from coming to the World's Fair. His view was supported by the published statements of several medical practitioners. There was very little fever, and that little was due to atmospheric conditions, to close alleys, to faulty drainage, to decaying refuse kept in cellars, to catching cold, to "grip," to everything, in short, except water. The water was all right, except after rain, and then it should be filtered. It was stated by the health commissioner that analysis showed the water to be pure. Nevertheless, Dr. Ranch was instructed to investigate the facts on behalf of a higher authority—the Illinois State Board of Health—and his report will be awaited with eager interest. Meanwhile, the official denials from the Chicago authorities appear to have ceased, but not the epidemic. It seems now to be admitted that there has, in truth, been alarming prevalence of enteric fever, as stated by Messrs. Sedgwick and Hazen, and that in January, 1892, there were no fewer than 311 deaths.

Unless the facts have been grossly misstated in the papers which have reached us, the action of the Chicago authorities is open to two explanations only—either they were culpably ignorant of local facts and records of the gravest importance to the public health, or else they disputed them knowing them to be substantially correct. It is difficult to say which hypothesis is the less creditable or the more calculated to destroy all confidence in their future statements or efforts.

On the evidence before us, we may point out that the *prima facie* case for water infection is a convincing one. The sewage of a vast city, a city in which enteric fever abounds, is poured into an inland sea. The drinking-water of that city is taken from points which are admittedly in unsafe proximity to the sewage outlets; moreover, it is open to question how far safety could be secured by merely increasing the distance. Enteric fever of a mild type has been for two years epidemic among the population supplied with this water. The alleged mildness of type only increases the terrible significance of the high mortality, and is a familiar phenomenon in water epidemics in this country. Under such conditions chemical analysis of the water can never prove safety, but may confirm the suspicion of danger, and it is announced that a recent official analysis was followed by an emphatic recommendation from the analyst that the water should always be boiled before use.

It is said that vigorous efforts are now being made to remove the intake to a point four miles from Chicago, far beyond any probable range of sewage pollution, and that the river-borne part of the sewage is to be prevented from entering the lake. The success of the World's Fair is likely to depend in no small degree upon the sanitary history of Chicago during the next few months. We may therefore assume that no endeavor will now be spared to discover and remove the causes of the epidemic, and to provide a supply of water which shall be free from danger of pollution by sewage. Dr. Ranch's high reputation is a sufficient guarantee that his part of the investigation will be thorough and complete; but, even if he should fail to find proof of the theory that the epidemic has been water-borne, the danger of the present mode of sewage disposal and water supply is manifest.

The evidence that the lake water is at present the source through which the typhoid fever prevalent in Chicago is conveyed convinces physicians generally, and the heavy typhoid mortality of January emphasizes the danger. There is a great demand for "pure" drinking-water derived from sources other than Lake Michigan, but it adds a new element to the danger of the situation that evidence is forthcoming in the local papers that in the localities from which "the peddlers of pure water" are observed to draw their supplies its purity is more than doubtful. What is sold as distilled water is declared to be "lake water" or its equivalent. A good deal of this is described as "sent out in tin cans or iron tanks," obviously dangerous methods of even attempting to carry pure water. It illustrates the extremities to which Chicago is reduced that there is much discussion as to the propriety of licensing retailers of "pure water" in order to have facilities of inspection. It is obvious that the drinking-water supply of Chicago is in a state exposing visitors as well as residents to great danger, and that those who visit Chicago for the "World's Fair" will do well to bear this danger in mind, and to be very sure that they do not drink "lake water," or any of the doubtful substitutes which are, it is alleged, being palmed off upon consumers who have taken the alarm, but are yet too easily satisfied with anything that is sealed in a bottle and calls itself pure.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

THE TROUBLESOME SYMPTOMS CAUSED BY ENLARGEMENTS OF THE EPIGLOTTIS,

AND THE ADVISABILITY OF REDUCING THE SIZE OF THIS CARTILAGE BY OPERATIVE MEASURES.\*

By CLARENCE C. RICE, M. D.,

PROFESSOR OF DISEASES OF THE NOSE AND THROAT IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL,

This subject is not a large one, nor is it one to which any great amount of attention has been paid by this association. Enlargements of the lingual tonsil and contact between such lymphatic hypertrophies and the epiglottis have been thoroughly studied and elaborated in recent writings.

The condition of the epiglottis in tuberculosis, in syphilis, and in lupus has received due consideration, and since the lesions of these diseases are frequently limited in a characteristic manner to the epiglottis, the epiglottis has probably been examined as carefully as any other portion of the respiratory tract. Great progress was made in the treatment of catarrhal affections of the top of the larynx when it was recognized that contact between the base of the tongue and the epiglottic cartilage occasioned such symptoms as tickling in the throat, a feeling of fullness in the lower pharynx, a disposition to swallow, and eventually paroxysms of coughing. It was found also that contact between the tongue and epiglottis was a sufficient irritant to cause a chronic catarrhal laryngitis.

In a paper entitled Unusual Causes of Coughing,† read before the Medical Society of the State of New York in February, 1886, at a time when I believe this subject had not been brought before this association, I noted that in the frequent condition of contact between the tongue and epiglottis, sometimes it was enlargement of the lingual tonsil which was the primary source of the difficulty, and sometimes it was some abnormality of the epiglottis which was at fault.

It was found that an enlargement of the lingual tonsil which overhung and rested upon the epiglottis caused at first a temporary congestion, and very soon a permanent congestion and enlargement of the epiglottis. I believed then, and my opinion has not been changed, that the contact of the epiglottis, either with the tongue in front or with the lateral walls of the pharynx, was the most frequent cause of those peculiar epiglottides which are the subject of this paper—epiglottides which are sometimes enlarged vertically, sometimes laterally, which are always congested, and which are prone to attacks of subacute inflammation.

To say that such epiglottides are simply an exhibition of a chronic catarrhal process which has affected the entire larynx does not satisfactorily explain the condition, for we have all noted that the enlargement and congestion of the kind of epiglottis here described are much more marked than are the evidences of a catarrhal inflammation within

the larynx proper. This epiglottis is frequently found enlarged when the remainder of the larynx is practically normal. And, again, whereas the appearances of congestion and swelling in the larynx will disappear when properly treated, the chronically enlarged and congested epiglottis either is not benefited at all by treatment, or, if improved, it quickly returns to its condition of congestion.

The fact that the epiglottis becomes congested and enlarged when the larynx remains in a healthy state, and also that these epiglottides are constantly fluctuating from a slight to a large degree of congestion, and even changing in the degree of thickening and lateral enlargement, the larynx as a whole remaining in a quiescent condition—these facts point strongly to the conclusion that the cause of the annoyance to the epiglottis is very limited in its action and is applied directly to the epiglottis, and is not one of the sources of general catarrhal inflammation which are to be found without the body.

In addition to the enlarged lingual tonsil which is the most frequent cause of enlargement and congestion of the epiglottis, there are a number of other factors to be mentioned as causative in the production of such enlargement. It is quite proper here to lay some stress upon predisposing causes and to say that the congenital formation of the epiglottis as regards size, shape, curvature, length, and breadth, determine largely whether it will be exposed to contact with neighboring parts or to external irritants. It is unnecessary to describe the normal epiglottis; we know that its direction is vertically upward and that its free extremity is curved forward toward the base of the tongue. It is undoubtedly true, as Merkel\* demonstrated by experiment, that the length of the epiglottis in man stands in a fixed relation to the antero-posterior diameter of the larynx, so that when the epiglottis covers the larynx during deglutition its margin escapes the posterior wall of the pharynx by the distance of a quarter of an inch. An epiglottis which is compressed laterally (see Fig. 1) can hardly be rubbed against by those lateral bands of

FIG. 1.

lymphatic tissue which form a connection between the faucial and the lingual tonsil, though its compressed corners may rest against the posterior wall of the pharynx, while a broad epiglottis—that is,

one of long diameter from side to side—is very apt to come in contact with the sides of the pharynx if there is any lymphatic enlargement (see Fig. 2).

Some epiglottides have such a sharp anterior curvature at their superior margin that they can hardly escape friction with the base of the tongue (see Fig. 3). We see the op-

\* Read before the American Laryngological Association at its thirtieth annual congress.

posite position of the epiglottis occasionally in health, when the laryngeal mirror shows it to be fallen over backward, covering the aperture into the glottis and resting against the posterior wall of the pharynx. This is the pendulous epiglottis (see Fig. 4), and Camalt-Jones\* says: "It is not a normal one, and its position is generally on account of

some throat trouble." In an interesting monograph written by Sir George Duncan Gibb,† in which he gives the results of his study of the effect of the pendulous epiglottis upon the voice and upon the general health, he states that

FIG. 2.

eleven per cent. of four thousand six hundred people examined were found to have this variety of epiglottis, and that every one of two hundred and eighty natives of India, China, and Africa had a pendulous epiglottis.

He thinks this is due to the relaxation induced by living in a hot climate. He emphasizes the evil effect of the pendulous epiglottis upon voice and health in that it causes a slight dyspnoea. I have quoted from this article only because it is an unusual one.

The large pendulous epiglottis is seen most frequently in disease, and the faulty position is due largely to the increased weight of the margin of the cartilage. In tuberculosis laryngis, for example, where the edge of the epiglottis is thickened many times, it is not uncommon to find the

cartilage lying far backward. The epiglottis will assume a more erect position as fast as the inflammatory weight is removed. This fact was shown to be true in a case of fibroma of the epiglottis; as the growth increased in size the cartilage was carried backward and downward, but it returned to its normal position when the growth was removed.

We see, too, epiglottides which are not symmetrical, one side of which extends nearer the lateral wall of the pharynx

FIG. 4.

than does the other side. More commonly we find a prolongation of the cartilage at either one of the superior corners (see Fig. 5). Occasionally there is a spur extending from a point midway in the superior margin of the epiglottis. I have always thought that these elongations of the epiglottis were due but slightly to congenital causes, but, commencing perhaps in this way, were irritated by contact with neighboring parts, and so the elongation became much more prominent than it otherwise would.

I do not know whether Dr. Donaldson\* was referring to the inflammatory epiglottis in his article on the Functions of the Epiglottis in Deglutition when he says:

"The epiglottis is frequently out of proportion to the size of the rima glottidis. The free edges of this various-shaped cartilage are of such different contour that they can not fit the margin of the glottis accurately."

The epiglottis normally and pathologically presents not more than five or six radically different shapes, but each of these has numerous shades of variation in form. Browne † says the epiglottis may be looked upon as the distinctive feature of the larynx, for no part is so variable in shape and size. Audubert, ‡ in Moure's clinic, made careful record of the different-shaped epiglottides, and published his results in twenty-eight plates.

Epiglottides of such curvatures, shapes, and sizes as noted in the illustration are strongly predisposed to congestive enlargements, on account of the injury they invite from contact with parts in the neighborhood. Undoubtedly there are other factors present which make it difficult, if not impossible, to diminish the congestion or to reduce the epiglottis in size.

An unusually high position of the epiglottis in the pharynx particularly exposes it during deglutition, and impurities in the respiratory current are more harmful to it than to an epiglottis of normal size placed lower down. These enlarged epiglottides always seem to be especially congested and irritable in people who use tobacco and alcohol freely. The degree of the congestion of the epiglottis seems to bear a very intimate relation with the condition of the middle pharynx. The color of the mucous membrane is apt to be of the same shade in both these locations. Disturbances in digestion, gastric disorders, are apt to fire up the chronically enlarged epiglottis. In fact, the epiglottis when in this condition seems to be more nearly related to inflammatory exacerbations of the pharynx than to those of the larynx. It is possible that the enlarged epiglottis owes something of its size to either venous or arterial congestion caused by pulmonary, cardiac, or hepatic disease. In two

‡ Audubert. *Annal. de la Polyclinique de Bordeaux*, January, 1888.

of my most marked cases, both occurring in men about fifty-five years of age, one suffered with emphysema and chronic bronchitis, and the other had a weak, fatty heart.

The variety of epiglottitis which I have tried to describe is not commonly seen. I am not speaking of epiglottides which have become moderately congested and slightly enlarged by the pressure of the lingual tonsil, but of marked hypertrophies of the epiglottis. I should say that I had seen ten or twelve cases, and three fourths of them in men. We should expect this preponderance in men, because of their having a larger degree of catarrhal inflammation of mucous membrane than women, and also because of the use of tobacco and stimulants.

Enough has been said as to the manner in which the epiglottis becomes at first congested and eventually permanently enlarged. As to the pathology, a single sentence will describe the condition: It is a pure hyperæmiosis effected by an abnormally large blood supply. The mucous covering becomes somewhat thickened, the superficial blood-vessels are increased in number and size, there is seldom any œdema, the enlarged epiglottis is hard and cartilaginous throughout its entire extent. No matter how much enlarged the epiglottis is, it always presents the appearance of the normal cartilage as regards texture so well described by Collier,\* who says that "on looking at the epiglottis from behind it is seen to be covered by a thin mucous membrane continued from the inner aspect of one aryteno-epiglottic fold to the other. Through the mucous membrane the well-defined and sharply cut edges of the epiglottis can be seen."

There are certain *peculiar* symptoms which are occasioned by an hypertrophied epiglottis, but it will hardly be necessary to depend upon any characteristic symptom, as the diagnosis of this condition will readily be made the first time a laryngeal mirror is introduced into the mouth. The constant tickling and feeling of fullness in the larynx, the hard, unsatisfactory paroxysms of coughing, which may be followed by glottic spasm or by vomiting, and the partial loss of voice which remains for a time—these point to laryngeal irritation and reflex phenomena. The symptom of "empty swallowing," spoken of by Gleitsmann † in cases of enlarged lingual tonsil, is common also where an enlarged epiglottis is present. These patients frequently give the history of having swallowed foreign bodies, and they have a strong belief that the uncomfortable feeling in the throat is due to their lodgment in the pharynx. These outbreaks of coughing occur upon the slightest provocation, when the patient is talking, singing, laughing, or eating, when he lies down or when he rises, and when he first goes out of doors. Paroxysms of coughing are not so easily produced in any other disturbance of the larynx or of the lungs. The long-continued mechanical violence caused by the cough usually gives rise to a very irritable mucous membrane throughout the upper respiratory tract, and in this condition the smallest external irritant is suffi-

cient to cause an explosion. It is not an encouraging task to control the unpleasant symptoms caused by an enlarged epiglottis in any patient, but it is especially difficult to do so in singers and in public speakers. Patients of this class are particularly unfortunate if their epiglottides are permanently enlarged, for not only will the use of the voice produce tickling, but the patient is so afraid of coughing that he holds the throat stiffly by muscular power, and this gives rise to a bad quality of tone. Fatigue of the voice is another symptom produced by an enlarged epiglottis.

Reflex cough caused by a very sensitive nasal mucous membrane, by accumulations in the auditory canal, by elongated uvula, by enlarged lingual tonsils, and by bronchial and pulmonary disease, should be distinguished from the cough due to an hypertrophied epiglottis.

It is only within the last year that I have treated these cases of large catarrhal epiglottides with any degree of satisfaction. If there is any astringent application which will cause any permanent reduction in their size, I have not found it. The atomization of the old mineral astringents and of tannic acid seems only to increase the irritation. Solutions of cocaine are of far more service, and I know of no better medical treatment than the application by spraying of a two-per-cent. solution of cocaine hydrochloride, followed by a coating of some one of the oily products, such as liquid vaseline, albolene, or benzoïmol; but these are only temporary in their benefit, and the constant use of cocaine in the larynx is to be avoided. I have tried strong solutions of silver nitrate after the spray of cocaine, but have made little progress. Patients of this class always return to the physician after a short interval. A slight change in the weather is usually sufficient to renew the disturbance in the top of the throat.

In my first case of operative treatment upon the epiglottis I used the galvano-cautery to diminish the size of an enlargement after I had in the same instance reduced the size of a lingual tonsil by the same method. But I would state strongly that burning is not the proper way of reducing the epiglottis. This cartilage resents such treatment to a remarkable extent; it becomes very much inflamed, œdematous, and painful, and weeks will elapse before the epiglottis recovers from the burning. The patient will be hoarse, but it is a little singular that, in spite of the fact that the epiglottis is so much swollen, the cough is less severe.

I operated with long-handled scissors in two cases, in both instances cutting off perhaps an eighth of an inch from the sides of the epiglottis, where they rested against the pharynx. The epiglottis was reached by using the tongue depressor alone. One of these two cases bled rather freely, but was checked by the application of a sixty-grain solution of silver. The inflammation following the scissor-cutting was moderate in both cases, and subsided in two weeks. The larynx was sprayed with a one-per-cent. solution of cocaine in oil. In view of the bleeding which is likely to follow the use of sharp scissors, curved or right-angled cutting forceps may be employed for removing a little from the sides or the top of the epiglottis. And here let me emphasize the direction that only a narrow margin of the epiglottis should be excised. The indication is

\* Collier. *Lancet*, 1889, i, p. 882.

† Gleitsmann. Hypertrophy of the Tonsil of the Tongue. *Medical Record*, December 17, 1887.

simply to prevent contact between the epiglottis and neighboring parts.

If both an hypertrophied lingual tonsil and an enlarged epiglottis exist, the lingual tonsil should first be reduced in size. When this source of irritation is removed the epiglottis will frequently lose something of its swelling and congestion. It is only as a last resort that the epiglottis should be reduced in size.

I quote an interesting case reported by Stookes\*—that of a child one year old who suffered for six months with paroxysms of glottic spasm and choking. Death followed, and it was found that the laryngeal obstruction was caused by an epiglottis which was a third to a half as long again as normal. Sir Morell Mackenzie, in one of his editions, speaks of his epiglottotome. I have not seen it, but believe an instrument of the proper curve, acting on the same principle as the tonsillotome, would be a useful one for this operation. There are a number of laryngeal cutting instruments where a knife is drawn across a circle which might answer the purpose. Dr. William Porter,† of St. Louis, in an article on Excision of the Epiglottis, refers to a case of growth upon the epiglottis which involved a large part of the cartilage. The epiglottis was removed with cutting forceps, and the inconsiderable bleeding was checked by applying a sponge wet with Monsel's solution.

In closing, let me repeat that there are many cases where such troublesome symptoms as fullness in the throat, tickling, voice fatigue, violent paroxysms of coughing, vomiting, and glottic spasm are caused by an enlarged, congested, irritable epiglottis. In most of these cases this condition of the epiglottis has been caused by an hypertrophied lingual tonsil, removal of which will afford relief. But in some few cases the epiglottis has become so enlarged as to rub against the lateral and posterior walls of the pharynx; and as no medication will reduce the epiglottis in size, it will be found necessary to take away a small portion of the margin of the epiglottis in order to prevent frictional irritation.

123 EAST NINETEENTH STREET.

## FRACTURE OF THE RADIUS.

NON-UNION.

RELIEF AFFORDED BY AN EXTENSION APPARATUS.‡

By CHARLES A. POWERS, M. D.

Miss C. M., a woman of fifty-three years, was brought to me some two years ago by Dr. W. H. Dustman for advice regarding a painful and partially disabled hand.

She had sustained a simple fracture of the right radius twenty-seven years previously, the repair being perfect and attended by complete restoration of function.

Sixteen years thereafter, or eleven years before I saw her, she had again broken the same bone, the seat of this latter fracture being approximately at the junction of its middle and

lower thirds. Union followed in this second instance, but the radial nerve became involved in the callus, and the fragments united with very considerable deformity. She suffered marked and continuous pain in the parts supplied by the radial nerve, and for the relief of this underwent an operation at the hands of a surgeon in the West, who cut down upon and freed the nerve.

Thinking to relieve the deformity in the radius, he made at the same time a section of the bone, adjusted the fragments, and wired them. Unfortunately, this operation was attended by suppuration and non-union of the fragments, although the freedom given to the nerve relieved the former pain. As time went by, the hand became more and more drawn to the radial side, the lower end of the ulna became quite prominent, and the patient suffered very considerable pain in the hand over the region supplied by the ulnar nerve. This pain was relieved by grasping the fingers and "drawing the hand down."

Her condition when she was brought to me was as follows: The right radius was an inch and a half shorter than the left; there was a false point of motion at about the junction of its middle and lower thirds. The fragments were freely movable, both dropping toward the ulna at the seat of fracture, the lower end of the upper fragment being somewhat behind the upper end of the lower fragment.

There seemed but little overriding; rather a loss of substance. Pronation and supination were short of complete. The grasp of the hand was less forcible than on the unaffected side. The hand was thrown well to the radial side, the deformity being shown in Figs. 1 and 2. The patient's chief complaint was of pain in the ulnar side of the wrist and hand. This was at times excessive, especially when she was fatigued, and at such times it occasioned almost complete disability. For its relief she was accustomed, as said, to draw the hand downward and to the ulnar side.

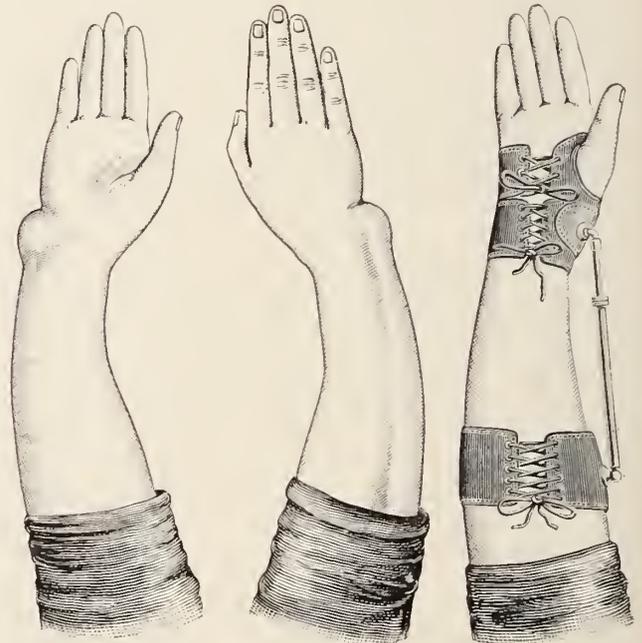

FIG. 1.

FIG. 2.

FIG. 3.

I was loath to advise an operative procedure, as it would very probably have necessitated resection of the ulna opposite the seat of fracture in the radius, and suggested the extension apparatus shown in Fig. 3, details in the manufacture of which were kindly cared for by Dr. Dustman.

It consists simply of two laced leather bands connected by a

\* Stookes. *Brit. Med. Jour.*, November 17, 1888.

† Porter. *Am. Jour. of the Med. Sciences*, April, 1879.

‡ The patient was exhibited some months ago, before the Orthopaedic Section of the New York Academy of Medicine.

double bar which is so arranged that it can be lengthened or shortened by a screw which traverses it. The upper of these bands grasps the swell of the forearm below the elbow; the lower goes about the wrist and upper part of the hand. The bar is inserted at each end in a joint which allows motion in all directions. By lengthening it the hand can be carried downward to a desired extent, and, as the chief pressure is at the base of the thumb, it is at the same time carried to the ulnar side. Reference to the cut will show that pronation and supination are easily effected.

The patient wore the apparatus continuously at first and averred that it gave her complete relief. She was able to resume duties which had hitherto been impossible. She has of late been able to dispense with it a part of the time, wearing it when fatigued or when obliged to use the hand more than usual.

35 WEST THIRTY-FIFTH STREET.

## CONCERNING THE ADENOID TISSUE OF THE PHARYNX AND NASO-PHARYNX.

BY JOHN DUNN, M. D.,  
RICHMOND, VA.

IN the fall of 1890 Mr. S., aged twenty-six, came to see me about his throat. History as follows: Seven or eight years previously he had had "an acute attack of sore throat," for which at the time he had undergone the treatment usual in such cases, including removal of part of the uvula. Since that time he had never been free from a sense of discomfort in his throat, which, often for months at a time, would remain acutely painful. The pain was not referred to any one place in the throat, but the "whole throat was painful." During these years he had submitted to all kinds of treatment, including "having the skin several times burned off his throat with caustic," removal of part of the left tonsil with cautery, and all the anti-sore-throat remedies of the pharmacopœia, and without relief. Examination at this time showed the mucous covering of the pillars of the fauces, soft palate, uvula, tonsils, pharynx, and part of the nasopharynx to be fiery red. There was no swelling of the parts; no exudation. Scattered over the pharyngeal wall were a few so-called "enlarged follicles." The left tonsil had been in a ragged manner destroyed by the application of the cautery, which had also removed part of the posterior pillar of this side. The right tonsil lay flat against the posterior pillar of the right side; this tonsil was enlarged, but not enough to protrude beyond the edge of the pillar; its epithelial covering, like that of the rest of the pharynx, was fiery red. I asked Mr. S. when his throat hurt him. His reply was: "It hurts all the time. It aches. It has been this way for years." There was no nasal complication, no upper pharyngeal complication, to account for this state of affairs. There had been some rheumatism in his family, but not enough to make its existence a part of the family history. In other respects Mr. S. was healthy. (I have since then discovered that Mr. S.'s skin is exceptionally liable to inflammatory action after the application of bichloride solutions or of any similar applications.) I advised the removal of the right tonsil, telling Mr. S. that there was a bare possibility that it might be the cause of his throat trouble, though I could not assure him that it was, or that its removal would afford him the relief he sought, as I had never seen a case similar to his (*i. e.*, a case of apparently acute inflammation of the coverings of the pharynx, including the soft palate, uvula, and pillars of the

fauces, which acute inflammation at the same time was chronic.)

He declined to have the tonsil removed, saying that it gave him no more pain than the rest of his throat. I then put Mr. S. on antirheumatic remedies, including salicylate of sodium. His throat got a little better after a time, probably as a result of time and not of the medicines.

In October, 1891, Mr. S. returned to my office saying that he could stand the pain in his throat no longer. If there was any possibility of the tonsil being the cause of his trouble he wanted it removed; something had to be done. Examination of the fauces showed exactly the same condition that existed a year before—the fiery redness of the mucous membrane. The right tonsil seemed to have decreased somewhat within the past twelve months, although it was still considerably hypertrophied. Examination of this tonsil showed that it was firmly adherent to, if indeed it had not been in part developed from, the outer part of the posterior faucial pillar. With the aid of a snare and a knife to loosen some of the adhesions, the tonsil was removed. After a day or two the throat began to lose its inflamed appearance and the pain in it to disappear. At the end of two weeks Mr. S. said his throat felt better than it had for months. There were, however, slight recurrences of the inflammatory condition of the mucous membrane during these two weeks, though of less severity than the attacks had been prior to the removal of the tonsil. Further treatment consisted in destroying with the cautery point the remains of the tonsil, which, owing to their position and adhesions, could be removed thus more easily than with a snare. Mr. S. also mentioned that, concomitantly with this sore throat, there comes a sore feeling in his chest just beneath the sternum; this soreness lasts all the time that the throat is inflamed, and seems to increase under exercise or exposure. Furthermore, Mr. S. says that the hearing of his right ear is not so acute as that of his left. Examination showed some retraction of the drum-head on this side. Three months after the removal of the tonsil Mr. S. says that the painful feeling in his throat has virtually disappeared; his throat, however, still tires easily, though he has not now the same desperate feeling in regard to it that he had when nothing he could do would relieve the aching misery that once proceeded from it.

Although the foregoing case at first glance bears only one point of interest—namely, a suggestion as to a relation between a hypertrophied tonsil and a chronic pharyngitis which remains for years more or less acutely painful—further consideration of its history brings up questions which, could they be answered correctly, would throw light upon the manner of disappearance of the hypertrophied adenoid tissue of the upper and lower pharynx, and the results upon the neighboring mucous membranes where this hypertrophied adenoid tissue has been allowed to disappear by natural processes. What constitutes a normal appearance of the upper part of the pharynx, the region of the so-called Luschka's tonsil, is still the subject of dispute. The well-known cut, after Luschka, given in Robinson's *Nasal Catarrh and Allied Diseases*, and in Bosworth's excellent work *Diseases of the Nose and Throat*, and elsewhere, gives no idea of what is to be considered a perfectly healthy upper pharynx; and a person possessed of a pharynx resembling this cut in appearance would be very grievously annoyed with "catarrh." Luschka's assertion that there is in the region of the pharyngeal vault always present a mass of this lymphatic tissue of about a quarter of an inch in thickness is not true. In the typically healthy upper pharynx

of the adult, at least, the mucous membrane is smooth, fits closely over the membrane beneath, and shows no such furrows and folds as are pictured in the above-mentioned cut. Judging from pathological conditions, these surface lymphatics of the pharynx are most numerous developed in the region of the vault, the chain extending to and even partly into the elevations of the Eustachian tubes on either side, running thence down the furrows behind the posterior pillars of the fauces. In severe cases of adenoids in the negro I have seen the lymphatics along the edge of the posterior pillars so hypertrophied as to give this edge a fimbriated appearance. (These cases have always been accompanied with phlyctenulæ and some form of facial eczema). While, naturally, the mucous membrane in which this lymphatic ring is found is less firmly adherent to the membrane below than that of the rest of the pharynx, I believe that whenever this lymphatic tissue is found in such amounts as to make "folds and furrows" there is some pathological condition present, either inherited or acquired. This, at least, seems to be true of the natives of this part of the United States. The typical Luschka's tonsil with its bursa pharyngea I have never seen but once, and then it occurred in a Prussian woman who had come to America to live. Whether true hypertrophy of these adenoids of the upper pharynx is ever congenital is to be doubted. One has as much right to expect to find congenital hypertrophy of the tonsils. This hypertrophy takes place most frequently in childhood, and not infrequently in early infancy. That, in some cases, the lymphatics of the upper pharynx are more developed at birth than in others is true, and it is further true that this adenoid tissue is in some individuals more liable to hypertrophy than in others; furthermore, it may not be doubted that in many, if not in the majority, of cases the tendency to hypertrophy of this pharyngeal lymphatic tissue is inherited. As Bosworth states, the stimulus of repeated colds seems, in these inherited cases, to be sufficient to cause hypertrophy of this lymph tissue. It may be asked, however, if the inherited tendency of this lymphatic tissue to hypertrophy is not itself sufficient to cause the hypertrophy; and, if so, is not the almost constant cold in the head, from which these cases suffer in childhood, the result of this hypertrophy? Apart from these inherited cases, this lymphatic tissue in other persons is liable to hypertrophy, especially under the stimulus furnished by measles and diphtheria. The worst of these cases are found after diphtheria, when the glands in the neck will be found also enlarged and will remain enlarged for years. It is not improbable in these cases that a specific poison is the cause of the hypertrophy rather than the inflammation to which the parts are subjected. The provision of Nature which prevents this adenoid tissue from growing indefinitely is to be commented on, though it can not be explained. Apparently there is no reason why, when this lymphatic tissue begins to hypertrophy, it should not grow until it fills all the empty space before it. In reality it does not do so, but when it has attained certain dimensions it begins to diminish in bulk. It is interesting to note that an acute inflammation of the third tonsil is rare. There are reasons for believing that it does occur in diph-

theria, in scarlet fever, and occasionally idiopathically. I have seen one case of acute inflammation of the pharyngeal tonsil following an operation for removal of a part of it. Rarely an abscess has been found in this tissue. I have seen one case. I have seen two or three cases of cyst which must have had their origin in this lymphatic tissue. At all events, this lymphatic tissue hypertrophies from various causes in childhood, often in early infancy. At what period of life it attains its greatest size depends upon the amount of this tissue present as a basis, inherited tendencies, and the circumstances attendant upon its development. I have seen these growths, under the stimulus of diphtheria, attain in a child where the inherited tendency was wanting several times the size it attained in another child who, from both father and mother, inherited this lymphatic throat. When once hypertrophied, if left to itself, this third tonsil disappears more or less slowly. I have seen marked amounts of it still present in a gentleman sixty years of age. In regard to the growth of this tissue there are some interesting points. In some cases, under the forceps, it feels almost like sponge, while on pressure it exudes a quantity of a juicy substance. In these cases there is probably an excessive development of lymphoid cells, great in proportion to the amount of the connective-tissue basis, and here there is little pain accompanying their removal. In other cases, the growths are more firm, cut readily under the forceps, and the cut piece comes away clearly, and is firm under pressure of the finger. In the third class these growths are tough, are very painful when removed, even under cocaine; have a tendency to tear under the forceps, and not infrequently one is forced to tear a small piece of the adjacent membrane of the pharyngeal wall with it. In these cases the pharynx is often painful after the operation. In the first two cases the patient suffers little or no inconvenience from the cutting. The third class of cases is generally found among those of the lymphatic temperament where the growths have existed for a long time, most generally in adults. There exists a tendency in all cases for these growths to decrease as the person gets older; in many cases to disappear. This latter occurs, it is probable, more rarely in the so-called "inherited" cases.

Having attained a certain size, these adenoid growths begin to diminish. Bosworth says: "Like other glandular hypertrophies, these growths show a tendency to apparently disappear at puberty. This may be explained by a diminution in the morbid activity of the tissues, and a certain amount of shrinking which occurs in this peculiar form of growth at this age, and also by the fact that they occupy a relatively smaller space in the now more widely developed pharyngeal vault." It is this "tendency to apparently disappear" that concerns us here, together with an endeavor to understand what is meant by "a diminution in the morbid activity of the tissues and a certain amount of shrinking which occurs in this peculiar form of growth at this age." Another point of interest for us is whether this so-called "tendency to apparently disappear" confines itself to the "adenoid growths," or whether it spreads to the adenoid layer, which is but the continuance of the layer from which these "growths" have their origin. The process by which

these growths disappear is in the majority of cases a slow one, continuing through years, so that we not infrequently find, and this especially in the "inherited" cases, it still incomplete in persons forty-five or fifty years old. In some cases the disappearance of these growths is much more complete and much less slow than in others. Many conditions seem to be here determining factors, and their relative importance is little well understood. It is probable that this "tendency to disappear" is not to be looked upon as the result of the "diminution of the morbid activity of these tissues," but as the result of the addition of repeated inflammations, whereby the lymph cells are partly absorbed and partly transformed into connective tissue; or, it may be that there results the formation of new connective tissue from the pre-existing connective-tissue cells, the basis of these growths, during which, in turn, the lymph cells are absorbed, while later the new formed connective tissue contracts. At all events, the relative amounts of lymph tissue and connective tissue in these growths change as the growths get older, the proportion of connective tissue continually increasing, and perhaps at the expense of the lymph tissue. It is probable, then, that repeated inflammations are the cause of this "tendency to apparently disappear." The surface position of these growths makes them especially liable to repeated inflammations, whereby there results a sclerosing process, which, when once established, is never at rest so long as there remains in them hypertrophied lymph tissue. In a certain proportion of these cases involution of these adenoids to the normal seems possible. In others, especially in the lymphatic constitutions, the sclerosing process sets in.

The reason why the involution to the normal of this hypertrophied lymph tissue takes place, and seemingly without ill effect, in the one, while in the other there sets in a sclerosing process accompanied by such unpleasant effects upon the hearing, must be sought to a greater measure in the difference of the constitution than in any process superadded by disease. This sclerosing process, however, occurs often enough in persons where the lymphatic tendency is wanting to show that certain conditions other than inherited ones can induce this sclerosis. The mucosa, lying beneath the epithelium of the pharyngeal mucous membrane and that lining the Eustachian tube and middle ear, is an adenoid tissue composed of loose cellular tissue infiltrated with lymphatic cells. This lymph tissue is of the same character as that of the lymphatic ring, except that it lacks in those aggregations of lymph follicles which characterize this latter. It is in this adenoid stroma that, it seems to me, must be sought the starting point of those changes which are the cause of deafness in the so-called "inherited" cases. Take, for example, a case which has inherited a tendency to hypertrophy of this lymphatic tissue of the upper pharynx. As a rule, the necessary stimulus to this hypertrophy, whether it be bacillus, the excess of blood in this tissue due to the process of "taking cold," or a chemical product the result of disintegration of the mucous secretions, is found early in life. Hypertrophy of this tissue follows, usually accompanied by a like hypertrophy of the faucial tonsils; when once hypertrophied, involution

does not occur immediately. These masses of hypertrophied lymph tissue, however, become smaller; the "tendency to disappear" makes itself felt. This "tendency" is, it seems to me, distinctly an inflammatory one, which is never at rest so long as there remains hypertrophied lymph tissue in these growths, and which is liable to exacerbations from time to time. The process resembles that occurring in cirrhosis of the kidney or liver. There are reasons for believing that this process of sclerosis, by which this hypertrophied tissue becomes smaller, is not confined to these hypertrophies, but spreads from them along the contiguous adenoid layer and thus reaches as far as the middle ear. It may be that the same causes that determine the hypertrophy of these adenoids of the naso-pharynx determine also an excess of cells in the adenoid stroma of the adjacent mucous membrane, in which case, when sclerosis of the growths sets in, it spreads or is determined more quickly in their adjacent mucous membrane. To sum up: The sclerosis in these growths, then, seems to me to be the direct result of repeated inflammations; this sclerotic process when once started does not cease as long as there remains lymph tissue in these growths; it usually continues for many years; its effects are not confined to the hypertrophies themselves; a similar process may be determined by it in the adenoid stroma of the mucous membrane lining the tubes and middle ear.

It may not be out of place just here to say a few words in regard to the views held as to the mechanism by which the deafness which often accompanies these adenoids, though it may not be complained of until these adenoids have existed for years, or until they have disappeared, is produced.

Bosworth, writing of adenoids of the naso-pharynx, says: "A plausible explanation of the (ear) symptoms is interference with the renewal of air in the middle chamber, caused by their presence in the pharynx. Any cause that interferes with free nasal respiration, if continued sufficiently long, is liable to cause impaired hearing. The method in which this occurs, I take it, is that nasal stenosis, arresting the to-and-fro current of air through the nasal passages, causes a stagnation in the pharyngeal vault, and necessarily a certain amount of rarefaction of air in this region. . . . As a result, rarefaction of air gives rise to a condition of hyperæmia of the mucous membrane, extending through the Eustachian tube to the middle ear; Eustachian orifice closed; air in the middle chamber rarefied; drum-head retracted." This is plausible, except that it is hardly ever, if ever, the case that the naso-pharynx has its exits so closed that there results a rarefaction of the air contained in it. Furthermore, I see no reason for believing that it is ever rarefied for such a length of time as to produce hyperæmia of the mucous membrane. The orifice of the Eustachian tube remains open, though the tube mucous membrane may be so swollen as to be impervious to air from the naso-pharynx; but in no case would I be willing to admit that this swollen condition of the tube mucous membrane is due simply to rarefaction of air in the naso-pharynx. Bosworth thinks it very questionable that in these adenoid ear cases the ear symptoms are due to

an extension of catarrhal inflammation, as advocated by Woakes, Fränkel, and others. If by "catarrhal inflammation" is meant the process in which there is an increase in proliferation and desquamation of the superficial mucous cells, with increased secretion, he is probably right, for, while deafness in these cases occurs frequently enough as the result of a catarrhal inflammatory process, I do not think it is the rule. That these growths are frequently sufficiently developed, and into the tube-mouth eminences to such an extent as to interfere with the movements of the tube mouth, and by their continued presence prevent development of the tubal muscles, no one will deny who has ever examined a sufficient number of cases of this affection.

The causes of deafness in these adenoid cases are more than one. In a not inconsiderable number of the cases it is due to acute catarrhal and purulent processes; but these cases do not concern us here. In another proportion of these cases it is the result of the development of this adenoid tissue into the tube eminences, and even into the tube mouths, preventing the normal movements of the tube mouth and producing closure of the tube, with its results, and this proportion of these cases is very much larger than one is led to suppose from the examination of the post-nasal space in adults. To give due importance to this cause of deafness from adenoids, one must examine the upper pharynx in young children, where there will be found, I should say, from one third to one half, probably more, of all the adenoid cases of any severity, this tissue so developed into the tubal eminences as to interfere with their movements. In the majority of these cases this excessive lymph tissue growth disappears from its encroachment upon the tube eminences, and there remains no trace of it in the adult; the damage to the hearing has been done—damage which, if left untreated in childhood, makes repair impossible in adult age.

In the third proportion of cases, where past closure of the tube can not be proved, where the acute catarrhal inflammation has not been present, the cause of the deafness, it seems to me, must be sought in a slow sclerosing process affecting the lymph cells of the adenoid layer of the tubal and middle-ear mucous membrane. This process varies in degrees of intensity and in the length of time requisite to produce marked change in the power of hearing. The length of time before and degree to which the hearing becomes impaired are dependent chiefly upon two causes: 1. The degree of resistance possessed by the lymph cells of the adenoid layer of the mucous membrane; this, the inherited part of the cause. 2. The character of the inflammations to which the hypertrophied adenoid tissue of the naso-pharynx is subjected, as well as that of the inflammations superadded in this layer itself. Here two phases of the question come up—the sclerosing process by which, in many cases, the hypertrophied adenomatous tissue disappears may, during its continued existence, cause the appearance of a similar sclerosing process in the adenoid stroma of the tube and middle ear and thus cause deafness; or the lymph cells of this layer may have so little resisting power that they take on a sclerosing process, not as a result of their proximity to a similar process in the adjacent hyper-

trophied adenoids, but as a result of repeated slight inflammatory attacks—*e. g.*, colds, etc.—the result in time of exposure. So it follows, in these third proportion of cases, if the deafness that accompanies adenoids of the naso-pharynx be due to a sclerosing process of the lymph basis of the tubal and middle-ear mucous membrane, caused by the persistent existence of a similar process in the adenoids of the naso-pharynx, then removal of these adenoids will prevent the deafness that follows when they are allowed to remain; if, on the other hand, the deafness be due to an inherited lack of resistance in the lymph cells of this adenoid layer of the tube and middle ear, although the removal of the hypertrophied adenoids be indicated for other reasons, we are not to hope that their removal will prevent deafness.

The case of Mr. S., related at the beginning of this article, shows in an exaggerated way how the whole lymphatic system of the upper throat may be affected by an inflammatory process at work in one part of the system where hypertrophy has taken place. Had we here to do with simply a painful throat and an acutely inflamed tonsil, the case would have nothing worthy of note; but we have a different thing—an enlarged tonsil (both having been enlarged, but one was removed), one which has been hypertrophied for seven years, accompanied by an apparently acutely inflamed mucous membrane of the whole throat, and a condition which for months at a time remained acutely painful. Removal of the tonsil does away, in a great measure, with the inflammatory appearance of the mucous membrane and altogether with the pain, while all other remedies proved useless. It is, then, fair to assume that in the tonsil was the cause of the inflammatory condition, and thus of the pain. The process that was going on in the tonsil was the development of connective tissue at the expense of the lymph tissue—an inflammatory process. The process affected the whole lymphatic layer of the upper throat, and it is not improbable that it had extended to the ear of the same side in which the tonsil existed.

## PERFORATION OF TYPHOID ULCER, WITH ADHESIVE AND PROTECTIVE PERITONITIS.\*

BY HENRY L. ELSNER, M. D.,

SYRACUSE, N. Y.,  
PROFESSOR OF CLINICAL MEDICINE, SYRACUSE MEDICAL COLLEGE.

IN presenting this paper to you for consideration I am prompted by the importance of the subject, the growing interest manifested by the profession for accurate clinical data relating to all unusual abdominal complications arising in the course of typhoid fever, and an appreciation of the fact that while much has been written and said, both by physicians and surgeons, on the indications for treatment of intestinal perforation, medical and surgical, the subject is still *sub judice* and requires a flood of light which can only be supplied by the study of many cases at the bedside and on the post-mortem table.

\* Read before the Medical Society of the State of New York at its eighty-sixth annual meeting.

While I am to report but a single case, I find, on consulting the literature of the subject, that it is sufficiently rare to demand your attention, and from it I feel that we can draw valuable deductions when associated with other experiences which have accumulated in the past.

On the 27th of October, 1891, Gottlieb G., German, shoemaker, aged twenty-seven years, was admitted into St. Joseph's Hospital, Syracuse, N. Y. Previously healthy, with negative family history. To all appearances he was a temperate man, well nourished, weighing about one hundred and eighty pounds. He was sent to the hospital by my assistant, Dr. Werfelman, whom he had consulted during the day and who diagnosed walking typhoid fever. We judged him to be well advanced in the second week of the disease, for there was already a well-marked and characteristic roseolar eruption on the abdomen. He had not been feeling well for three weeks, during which time he had nose-bleed at frequent intervals, felt nauseated, vomited several times, and had all of the usual manifestations of approaching disease. He had no chill, but had felt hot and feverish while at his work; had no diarrhoea before entering the hospital, but complained much of constipation.

On admission, we found the characteristic apathy of typhoid, tongue dry and heavily coated, abdomen slightly distended and tympanitic, with but little pain on pressure in the right iliac region. A considerable amount of hypostatic congestion was found at the base of both lungs. Temperature 103.2° F., pulse 93, respiration 22.

During the following seven days there were no noteworthy symptoms, the temperature was easily controlled, never rising above 103.8° F., the pulse rarely exceeding 100, usually between 90 and 100. There was but little delirium, no diarrhoea, and aside from the roseolar eruption which persisted, and the usual tympany found in like cases, no positive symptoms.

He had been carefully watched and nursed, kept on a liquid diet without antipyretics, treated with intestinal antiseptics. On the morning of November 3d, while making my daily visit, I noticed a decided change in the appearance of the patient. The facial expression denoted serious trouble; it was anxious, with eyes sunken. He was having constant hiccough, vomiting of a dark-green fluid, and complained of pain, not severe, however, in the upper right corner of the hypogastric region. His pulse, from 90 the night before, had by noon reached 120, while his temperature was 103° F. Physical examination of the abdomen gave increasing tenderness on pressure in the right inguinal and adjacent hypogastric region, while the neighboring regions were tympanitic. By afternoon a well-marked dullness on percussion was found in the right half of the hypogastric region, extending into the right inguinal region, though at this time palpation did not reveal the presence of a tumor. It was noticed that for eight hours there was anuria which was followed by scanty urination; no movement of the bowels during the day. At times during the night of November 3d his pulse reached 140, his hiccough and vomiting continuing without sufficient pain to demand administration of opiates.

On the morning of the 4th patient's general appearance was not improved. The anxious expression was still present, his extremities were cold, the hiccough and vomiting continued. It was now evident, on making a physical examination, that he had a tumor, the largest portion of which was situated in the right upper half of the hypogastric, slanting downward into the right inguinal region. This was plainly and easily outlined by palpation and percussion. It was not exactly in the position usually occupied by a tumor associated with disease of the vermiform appendix, and the McBurney point could not be found. The symptoms simulated an appendicitis so closely, however, that

one was almost tempted to make that diagnosis. On taking into consideration the rarity of such a complication with typhoid, in spite of the frequency with which it has been diagnosed, the presence of the tumor in a somewhat anomalous position, the absence of the McBurney point, the unusual amount of vomiting and hiccough, with at this time no evidence of perforation, and the general condition of the patient, a diagnosis of localized peritonitis over a typhoid ulcer, with adhesion to a neighboring coil of intestine, was made. Temperature 100.5° F., pulse 124.

During the day there was no material change in the condition of the patient. The pulse continued rapid, averaging 140, with rapid thoracic breathing, somewhat more tympany over lower half of abdomen; no movement of bowels. Urine scanty, not albuminous.

On the morning of the 5th he was brought before my class for clinic. His temperature had fallen to 97.2° F. and remained there during the day; his pulse was 111 to 140, respirations 30 to 40; extremities cold, wrists cold, less hiccough and vomiting. The tumor was still present, as easily outlined as the day before. His bowels moved during the day. A careful examination was made of the abdomen. In spite of the decided fall of temperature, no other evidence of perforation of typhoid ulcer was present. Liver dullness was not effaced. At the clinic it was concluded that we had a perforation of the ulcer, following the localized peritonitis, the escape of gas into the free peritonæum prevented by sufficient plastic exudate and recent adhesions. During the afternoon it was found that while tympanites in the lower half of the abdomen was increasing sufficient to make the detection of the original tumor impossible, there was still persistence of liver dullness.

*November 6th.*—Patient much more comfortable, with temperature 97.5° F., pulse 111. Lower half of abdomen still tympanitic; tumor lost; its position could no longer be determined, its previous area yielding tympanitic percussion. Toward night temperature gradually rose to 99.2° F., pulse 100. Bowels had moved during the day. No opiates were administered at any time, that the symptoms might not be masked; besides, there were no indications for their administration.

During November 7th and 8th there were no decided changes in the patient's condition. His temperature remained above normal, pulse improved in character, though equally rapid as before; his bowels moved; mind remained clear; tympany slowly subsiding, so that on the morning of the 9th, though his temperature was 101° F., pulse 123, he was looking much better and the original tumor was again palpable and in the same position as originally found. His hiccough and vomiting had ceased; he could lie on his side, while before he had rested on his back. We had now commenced to doubt the correctness of our diagnosis and were ready to take a more favorable view of the case than heretofore.

The morning of the 10th found our patient in better condition than we had left him the previous night; his temperature 99°, pulse 110, facial expression good, abdominal walls lax, no tympany, physical signs of original tumor present.

During the day, from 3 p. m. to 8 p. m., he had five large intestinal hemorrhages, and died almost exsanguinated at 8 p. m.

*Post-mortem* (made by Dr. F. W. Sears, pathologist, St. Joseph's Hospital, assisted by Mr. Hawley, student).—There was nothing noteworthy in the appearance of the body; our attention being called to the abdomen by the symptoms, it alone was examined. On opening the abdomen, the intestinal coils were considerably dilated, and the peritonæum was abnormally congested and lusterless, without evidences of general peritonitis, save in a few spots where a small amount of plastic exudate was noticeable. In the right half of the hypogastric and the right inguinal regions were found well-marked evidences of recent

plastic and circumscribed peritonitis. A coil of the ileum, beginning about five inches above the ileo-cæcal valve, had folded itself against the head of the colon laterally, and was there firmly held by the recent products of inflammation. Nowhere in the free peritoneal cavity did we find evidences of any escape of intestinal contents. This coil of ileum was everywhere surrounded by fibrinous and purulent material sufficient to incapsulate it and separate it from the free peritoneal cavity, while it rested against the colon on a pillow of almost completely organized fibrinous material. On raising this coil slowly and carefully from its resting-place without much force, the escape of air from the intestines was plainly audible. On closer examination, it was found that there existed in the portion of the intestines resting directly against the colon a perforation of a typhoid ulcer about two centimetres in length, and it was furthermore positive that the peritonitis had spent its greatest force around this ulceration.

Other portions of the intestines were examined, also the colon, with a view of determining the origin of the fatal hæmorrhages, without satisfactory result. Our clinical diagnosis, therefore, was corroborated by the anatomical appearances. So perfectly was the perforation sealed by the adhesive and protective peritonitis that no gas escaped during the post-mortem until the ileum was lifted from its resting-place, when it was found that the perforation itself had not closed, but was simply sealed by its fortunate position against the colon, where Nature's process held it.

There was no escape of fæces in the inclosure made by the adhesions.

It appears to me that in this case we have several features of unusual interest. The fact that a localized peritonitis over a typhoid ulcer may exist before its perforation and protect the free peritoneal cavity is in itself sufficient to claim more than passing notice.

The other interesting features of the case are the length of time that the patient lived after perforation, the gradual improvement preceding the fatal hæmorrhage, the continuation of the performance of intestinal function, the existence of the tumor, the absence of effacement of liver dullness, and the unhappy termination of the case by copious intestinal hæmorrhages.

Griesinger,\* many years ago, when he wrote his memorable article on typhoid fever, in Virchow's *Pathologie und Therapie*, spoke of just such cases as this. The following is a literal translation: "Evidently, in consequence of deep ulceration from within and sloughing, there frequently results, even before perforation, a localized inflammatory process, with adhesions of the inflamed patch to the neighboring intestinal coils. In such cases there is not at once perforation into the free peritoneal cavity. There is, however, a formation of circumscribed exudation, with or without supuration, which may ultimately lead to general peritonitis, though it may possibly remain circumscribed and gradually end in recovery. If there has been no adhesive process before the perforation, gas and intestinal contents escape into the free peritoneal cavity, and general peritonitis immediately results."

It was a similar case which first led Buhl † to suggest

the possibility of recovery after perforation of a typhoid ulcer. This, I believe, was in 1857. In Buhl's case death occurred on the forty-fifth day of the disease and twenty-three days after perforation. In this case, as in mine, the perforation was not the immediate cause of death, his patient dying as the result of hæmorrhage from a small artery opening into the intestine near the piece of mesentery which covered the hole. In Buhl's case, however, the hole was completely closed. The report of this case at my command does not mention the manner of closure.

There can be no doubt, and some of us could corroborate the fact by clinical experience, that a localized peritonitis without perforation around a typhoid ulcer may exist, giving rise to sufficient adhesion and inflammatory products to form a tumor which, for reasons which I will enumerate further on, simulates appendicitis.

In this connection I wish to say a few words in regard to the differential diagnosis between such tumor formation as was found in the case reported and appendicitis, and the prognosis of such cases. In a very interesting and instructive paper, recently read before the Association of American Physicians by Professor Fitz, of Harvard University,\* he says: "Most cases of recovery from symptoms of perforation of the bowel in typhoid fever are those in which an attack of appendicitis is closely simulated, while the fatal cases of perforation of the bowel in typhoid fever are, in the great majority of instances, those in which other parts of the bowel than the appendix are the seat of a perforation. Hence the prognosis of apparent perforation in typhoid fever is to be regarded as the more favorable the more closely the symptoms and course resemble those of an appendicitis."

You will kindly note that the author uses the words "simulate" and "resemble." This, it appears to me, is a happy use of the words.

While the diagnosis of appendicitis in typhoid fever has been frequently made, anatomical proof is wanting to establish such diagnosis. While there is some difference of opinion with regard to the exact proportion of cases of appendicitis occurring in conjunction with typhoid fever, anatomical evidence would not place the proportion above three per cent.; thus Fitz, † in collecting one hundred and sixty-seven cases of perforated bowel in typhoid fever, found but five cases, or a little less than three per cent.

Murchison ‡ found it but once in thirty-nine cases. Other authorities, among them Morin, § found perforation of the appendix in 18.75 per cent; Hesehel, || in 14.3 per cent. It is difficult to reconcile these great differences of the various writers. In New York, at least, where, according to Professor Lange, ^ appendicitis occurs with such astonishing frequency, it would be easy to establish the fact of ulceration and perforation of the appendix with typhoid fever if it existed.

The records of hospitals and the experiences of physicians fail to establish that fact. It is safer, therefore, for us as clinicians and therapeutists to adopt the statistics of Fitz.

Reasoning from our daily clinical and growing experiences with perforative appendicitis, we must conclude that if perforation of the appendix in typhoid fever is of such frequent occurrence, that fact ought necessarily to be established by positive pathological appearances.

Perforative appendicitis without typhoid fever is, as a rule, a fatal disease unless relieved at once by surgical art. Why, then, in typhoid fever should a perforated appendix give a more hopeful prognosis? There is but one way in which the clinical fact that perforation simulating appendicitis gives a more favorable prognosis can be explained. The usual seat of perforation in typhoid fever is located in the ileum, the larger number of perforations near the ileo-cæcal valve; but few perforations exist without more or less plastic exudate. The adhesion of coils of ileum near the colon, as in my case, would necessarily simulate appendicitis. This is the only clinical explanation which can be offered.

Among the differential points to be taken into consideration in the diagnosis of appendicitis from typhoid perforation we must consider the more sudden onset, as a rule, of general peritonitis without preceding appendical tumor, the profound change in the facial expression of the patient, the absence of the McBurney point, and the persistence in many cases of anuria for from eight to twelve hours or longer.

In doubtful cases a rectal examination might be of assistance. Certainly the previous history and the pulse and temperature chart would be considered as factors in reaching a conclusion. Simple perforative appendicitis would be sudden, without preceding malaise or evidences of approaching sickness. The occurrence of such an accident as reported in this case could be more readily diagnosed in an afebrile condition than at a time when the typhoid process is at its height. Such cases as these teach us the value of oft-repeated and careful examinations of the abdominal viscera in typhoid fever.

There is still another point which I wish to bring to your notice in conjunction with this case. It is the persistence of liver dullness in spite of the fact that we had intestinal perforation. To those of you who have studied the views of the various writers on this subject it must appear surprising to find such a wide difference of opinion as to the value of effacement of liver dullness in cases of perforation or air in the free peritoneal cavity.

Flint\* wrote a paper in which he held that effacement of liver dullness was one of the most characteristic signs of perforation. In his paper he reports the case of a young woman who developed an acute, diffuse peritonitis in the course of typhoid fever, with persistence of hepatic dullness, from which fact he concluded that intestinal perforation had not taken place, and from the fact that death did not occur until a week after the occurrence of peritonitis.

\* *Medical News*, Philadelphia, 1882, vol. i, p. 150.

As there was no autopsy in this case, the diagnosis may be doubted. The time of death ought not to weigh in the diagnosis. The differences of opinion with regard to the effacement of liver dullness, it appears to me, can be reconciled if we take into consideration the two great sources of error:

1. An unusually distended transverse colon by its presence between the liver and abdominal wall, yielding on percussion tympany anteriorly over the area of normal liver dullness without perforation existing.

2. Perforation in those cases where, as the result of adhesive inflammation, incapsulation, bands, or from other causes, air or gas is held within a circumscribed area or in the lower half of the abdomen without effacement of liver dullness.

The careful examination of the abdomen would reveal the presence of the first source of error by placing the patient upon the left side and percussing in the axillary line on the right side over the liver from the eighth rib downward, the presence of free air in the peritoneal cavity showing itself by a disappearance of dullness in that line, while there would be a persistence of dullness if the anterior tympany had been caused by the distended transverse colon.

This manœuvre has frequently assisted me, and is mentioned by Leube\* and Gerhardt† as a valuable means of diagnosis.

In the case here reported we had in the persistence of liver dullness, in conjunction with the other symptoms which the case offered, abundant evidences of a perforation, so that while we are all agreed that with air in the free peritoneal cavity we have in effacement of liver dullness a most valuable aid in strengthening the diagnosis of intestinal perforation, the presence of liver dullness, with symptoms of perforation, would lead us to suspect protective adhesion or sufficient incapsulation.

My case is another one to be added to the list of those which must materially affect the prognosis of typhoid perforation. The anatomical appearances were sufficient to convince all those present at the autopsy that the cause of death was in no way traceable to the perforation.

Finally, the question of surgical interference in this class of cases must be taken into consideration. I would not weary you with a single word in connection with that subject had I not seen the article recently written by Van Hook‡ on Laparotomy for Intestinal Perforation in Typhoid Fever, in which the author reports three cases operated upon, one of which was successful.

Among his conclusions, he says that "there is no rational treatment for perforation in the course of typhoid fever except laparotomy. . . . The only contra-indication is a moribund condition of the patient."

He also says that "the symptoms of peritonitis should not be awaited before operating." It appears to me that these conclusions are too extreme, can not be safely fol-

lowed, and do not take into consideration the possibility of preceding adhesive and protective peritonitis to guard the general peritonæum and the possibility of recovery from such an accident.

It would be far safer for us to follow the more conservative course of Da Costa,\* who, in the recent discussion on the subject, said that he would "never sanction an operation for perforation unless a causal appendicitis could be clearly made out, or for the relief of a patient from peritonitis."

The conclusion reached by Fitz † must have some weight in our decision, inasmuch as his thorough study of the subject gives his opinion great value. He opposes immediate laparotomy for the relief of suspected intestinal perforation, advising it only in the milder cases of this disease. "In all others, evidences of a circumscribed peritonitis should be awaited, and may be expected in the course of a few days."

If this condition requires surgical interference, it will be well for us to delay until the strength of the patient warrants it.

*Conclusion.*—1. A localized peritonitis over or in the neighborhood of a typhoid ulcer may exist without perforation.

2. Localized adhesive and protective peritonitis over or in the neighborhood of a typhoid ulcer may precede perforation and protect the free peritoneal cavity.

3. In some cases coils of intestine may become adherent, giving rise to tumor formation.

4. Symptoms simulating or approaching perforative appendicitis may exist, making a diagnosis between appendicitis and typhoid perforation with adhesions difficult.

5. Anatomical research proves conclusively that perforative typhoid appendicitis is exceedingly rare.

6. The prognosis of typhoid perforation is more favorable in proportion to the amount of circumscribed peritonitis and the nearness with which ordinary appendicitis is simulated.

7. Localized peritonitis preceding perforation and ultimate perforation can be diagnosticated in some cases.

8. Persistence of liver dullness does not preclude the possibility of intestinal perforation. Air and gas may escape into the lower abdominal regions and be held there by adhesions without changing liver dullness.

9. With effacement of liver dullness we must make sure by physical examination that such change is not due to the presence of an abnormally distended transverse colon.

10. Surgeons are not justified in performing laparotomy for the suturing of perforated typhoid ulcers if circumscribed peritonitis of an adhesive or protective character exists or is in process of development.

**The Presbyterian Hospital.**—We learn that at the annual meeting in April the managers will make the following appointments: Three additional visiting physicians, an additional consulting surgeon, and several consultants in special departments.

## A NEW INSTRUMENT FOR QUICKLY DETERMINING REFRACTIVE ERRORS OF THE EYE.

By ELMER STARR, M. D.,

BUFFALO, N. Y.,  
LECTURER ON OPTHALMOLOGY IN THE MEDICAL DEPARTMENT OF  
THE UNIVERSITY OF BUFFALO.

THE refraction of an optically perfect eye is such that parallel rays of light entering it are brought to a focus on its retina. Any deviation from this condition constitutes an error of refraction, and requires for its correction some variation of the luminous rays from parallelism.

The generally adopted method of determining the refraction of the eye is to use test types placed at such a distance that the rays of light emanating from them may be regarded in practice as parallel; and the deviation from parallelism necessary to correct a refractive error is effected by placing a lens in front of the eye. Besides this procedure there are many other methods of changing the course of luminous rays coming from a test object. The single convex lens is the simplest means of varying the direction of luminous rays, and has for this reason been often used in optometry.

If an object is placed at the focus of a convex lens, the rays of light coming from this object will, after passing through the lens, be parallel. The farther the object is removed from the lens, the more the rays will converge after passing through it, and in this way the deviation necessary to correct an hypermetropia may be obtained. On the other hand, if the object is brought from the focus nearer to the lens, the rays which leave the lens will be divergent; and this change is such as to adapt it to the refractive condition of a myopic eye.

Cocius, Smee, von Graefe, Badal, and others have made use of this principle in constructing optometers, the test objects of which consist of threads or lines, or of letters and figures placed at the focus of a lens of three or four inch focus.

All these optometers have the disadvantage that they provoke a certain effort of accommodation, inasmuch as the observer is conscious of the proximity of the test object. It is important that the accommodation be excluded in determining the static refraction of the eye; otherwise, the dynamic being added to the static refraction, the real error may be masked.

Then, too, some of these instruments do not serve to determine the visual acuteness because of the change in the size of the retinal image which they produce; the measure of visual acuteness is given by the size of the retinal image, and the acuteness of vision in one eye is comparable with that in another only when we know the size of the smallest retinal image that each can distinguish.

An optometer is fitted for the simultaneous determination of visual acuteness and refraction only on condition that the retinal images of all eyes examined by it have the same size.

The instrument here described fulfills these conditions completely, and has none of the disadvantages of the single convex lens.

The instrument consists of a cylindrical tube about 15 ctm. long, mounted on a stand, which admits of its being regulated for height and inclination. Within the tube a 16 D. convex lens (P, Fig. 1) is fixed, at a point  $6\frac{1}{4}$  ctm. from the proximal end; that is, at just the focal length of the lens. Beyond the convex lens, and moved by means of a rack and pinion, is a concave 16 D. lens (M, Fig. 1). The effect of this concave lens is to render parallel rays divergent, but this effect is neutralized by the convex glass when the two lenses are in contact. When, however, the two lenses are separated from each other, the convex glass more than neutralizes the divergence caused by the concave glass and the rays are made to converge. The action of the system will be better understood by reference to Fig. 1.

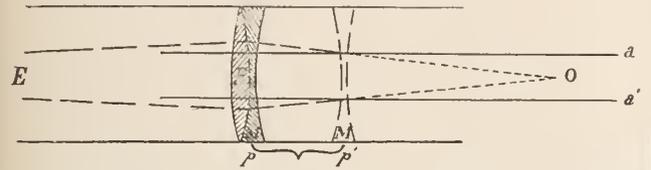

FIG. 1.—When M and P are in contact, rays  $a a'$  continue in their original direction. The effect of moving M from  $p$  to  $p'$  is shown by the broken line.

The eye whose refraction is to be tested is situated at the end of the tube at E. The effect of the concave lens M upon the parallel rays  $a a'$  is to cause them to diverge, so that they leave the glass in a direction as if they came from the point  $o$ , which is the focus of the lens M, which in this case is  $6\frac{1}{4}$  ctm. in front of the glass. The effect of the convex glass P, then, upon the rays  $a a'$  is the same as if the rays proceeded directly from the point  $o$ ; in fact, the point  $o$  may be considered, in this respect, as the object. Now, as already stated, when an object is placed at the focus of a convex lens, rays of light coming from this object will, after passing through the lens, be parallel; and if the object be removed from the lens the rays will converge after passing through it. So that, if the lens M be brought into contact with lens P so that  $o$  falls in the focus of lens P, the rays  $a a'$  will leave P parallel; and if the lens M be moved away from P so that  $o$  falls outside the focus of P, the rays  $a a'$  leave P convergent, and the amount of the convergence depends upon the distance of  $o$  from P—that is, upon the distance the lenses M and P are separated. Calculation shows that for every  $\frac{1}{2}\frac{9}{16}$  ctm. the lenses are separated, the effect is the same as a one-diopter convex lens, or + 1 D.; or a separation of the glasses 6.25 ctm. is identical with a + 16 D. lens.\* It will be seen, then, that

\* The formula for determining the effect of a given separation of the lenses in this instrument becomes the same as the formula for determining the point at which the image made by a convex lens falls when the distance of the object from the lens is given. For the focus of the concave lens is virtually the object, and its distance from the convex lens manifestly depends upon the distance the lenses are apart.

Let  $f$  denote the focal length of the convex lens P;  $d$ , the distance of the object (focus of concave lens) from P; and  $x$  the focal length of the resulting combination.

Then the equation  $\frac{d-f}{f} = \frac{f}{x-f}$  will give the value of any given movement of the concave lens M.

Suppose the lens M be moved away from P 0.25 ctm.; then the dis-

every possible degree from zero or nothing up to + 16 D. can be obtained with this combination. For any concave or minus combination it is only necessary to place in the proximal end of the tube at E a minus lens of such power as to neutralize the converging rays coming from the lens P when M and P are  $6\frac{1}{4}$  ctm. apart. That is, when the lenses stand in this position, their effect is just neutralized by a concave 16 D. lens placed in the end E of the instrument, and the rays of light then leave this lens parallel again and the combination once more stands at zero. If now the lenses M and P are brought nearer together, the result is a combination weaker than + 16 D., so that the concave lens at E more than neutralizes this effect, and the rays leave the instrument divergent, or as they would after passing through a single concave lens; so that by this means every possible degree from 0 up to - 16 D. can be obtained.

In practice the tube of the instrument is graduated with a scale showing dioptries and half-dioptres, and the frame of the movable lens M carries a pointer which indicates the number of dioptries corresponding to the amount of separation of the glasses. A disc having a stenopaic slit and fitting into the end of the tube serves to determine the refraction of each meridian of the eye separately.

The advantages of this combination are decided, as it allows of the use of the ordinary test type placed at the usual distance, so that no effort of accommodation is caused by the proximity of the test object. Then, by this arrangement, the anterior focus of the eye is kept at the focus of the convex lens of the instrument, so that no enlargement of the test object is produced. In other words, the conditions are most favorable for determining the actual refraction of the eye.

174 FRANKLIN STREET.

**The Sense of Equilibrium.**—"Our Vienna correspondent," says the *Lancet*, "writes as follows: At a recent meeting of the Vienna Society of Physicians, Dr. Kreidl, Professor Exner's assistant, reported on the experiments he had made on deaf mutes concerning the physiology of the labyrinth. Touching the experiments made on this subject by Flourens, Goltz, Mach, and Breuer, he pointed out that the membranous canals of the internal ear should be regarded as the peripheral part of the mechanism of the sense of equilibrium, the sensations of the disturbance of which he takes to be produced by the flow of the fluid in the ampulla and in the membranous canals. If the views of physiologists on the function of the otoliths and the membranous canals be true, it would have been expected that anomalies of the sense of equilibrium should be found in deaf-mutes. Purkinje had previously observed that if a person is made to rotate on his own axis the eyeballs were moved to the side as in nystagnus. This in Dr. Kreidl's experiments was not observed in deaf-mutes to any very large extent. Dr. Kreidl from other experiments is led to regard the otolithic organs as a statical sense."

tance of object is 0.25 ctm. + 6.25 ctm. (focus of M); or  $d = 6.50$  ctm. Focus of P = 6.25 ctm., or  $f = 6.25$  ctm.

Substituting these values in the equation, we have

$$\frac{6.50 - 6.25}{6.25} = \frac{6.25}{x - 6.25}, \text{ whence } x = 162.50.$$

That is, the focus of such a combination falls 162.50 ctm. behind the lens P. But the lens P is placed 6.25 ctm. in front of the eyehole of the tube, hence the focus falls 162.50 ctm. - 6.25 ctm. = 156.25 ctm. behind the eye. A glass of 156.25 ctm. focus is  $\frac{1}{1.5625}$  of a diopter, or 0.64 D. Therefore, separating P and M 0.25 ctm. equals + 0.64 D. From this it is easily calculated that the effect of moving M  $6\frac{1}{4}$  ctm. away from P. is equal to a + 16 D. lens.

## NEW OBSERVATIONS IN THE USE OF SULPHONAL.\*

By S. GROVER BURNETT, A. M., M. D.,

KANSAS CITY, MO.,  
LECTURER ON DISEASES OF THE MIND AND NERVOUS SYSTEM,  
KANSAS CITY MEDICAL COLLEGE;  
CONSULTING NEUROLOGIST, MISSOURI PACIFIC RAILWAY HOSPITAL;  
VISITING NEUROLOGIST TO ALL SAINTS HOSPITAL.

SINCE the advent of sulphonal into the domain of our therapeutics in 1888—for before this it was rather more of experimental than of therapeutical use—I have been an untiring advocate of its known superiority over other hypnotics, as well as a diligent student in searching out other qualifications with which we are not familiar. Hence in this brief review it is only intended to mention developmental features.

In the *New York Medical Journal* for March 2, 1889, I reported, in connection with a tabulation of cases illustrating the experimental use of sulphonal, my first case of poisoning by this drug.

CASE I.—This patient was a chronic melancholiac, fifty nine years old, and suffered from arterio-sclerosis, with compensatory cardiac hypertrophy. The drug had been given her in repeated doses to overcome the insomnia of melancholia agitata, without any good results (see *Points on the Use of Sulphonal*, by the writer, in the *Kansas City Medical Index*, August, 1890). At that time we were told to give almost any quantity without fear, and some three thirty-grain doses were given during the night. When called to see her in the morning she was quite cyanotic; respiration, 16 and of a labored character; temperature, 98° F.; with a weak, compressible pulse of 60. She lay in a comatose state all day, and was not able to walk for some ten days or more. Inco-ordination was so great that she remained helpless so far as locomotion was concerned. The reflexes were not examined.

CASE II.—This case was that of a robust married lady of thirty years, who at this time was suffering from an acute attack of dysenteric diarrhoea. A part of the treatment prescribed was the use of ten-grain doses of salol every two hours and the recumbent posture. She took the first dose at 6 A. M. At noon a messenger called, saying Mrs. C. was in a deep sleep, and asked if the medicine would cause it. I replied in the negative, and expressed my pleasure to hear of her resting so well, at the same time requesting that she be not molested, only to give her the powders. At 8 P. M. her brother alarmed me by saying Mrs. C. could no longer be awakened, and, unless something could be done, her condition was becoming critical. I knew something was in error, for no narcotics had been prescribed. The countenance presented a peculiar blanched, cyanotic aspect, which immediately recalled one other case (just mentioned) of sulphonal poisoning, for which I was accountable, I supposed, and which has been reported. Examination of the medicine revealed the fact that the apothecary had put up sulphonal instead of salol, of which seven ten-grain doses had been taken, making in all seventy grains. The pulse was 55, full and bounding, but not strong; respiration, 14; temperature, 98° F.

This case was observed in 1889, and all cases of sulphonal poisoning coming to my notice have been characterized by lowering of temperature. Just what significance the temperature may have here it is difficult to say, as it registered 102° F. in the morning, and any conclusion would simply be a supposition.

\* Read before the Medical Society of the Missouri Valley, at Lincoln, Nebraska, December 17 and 18, 1891.

Any such profound state, unless arising from acute causes, might present a perceptible lowering of temperature without causing surprise. Some two hours elapsed before any voluntary movements or attempts of recognition on the part of the patient were made, notwithstanding she was being stimulated and fairly dragged about the room. Efforts at resuscitation were kept up some four hours before intelligent attempts to answer questions were made, and as soon as left to herself she went into a deep sleep again. The next day the patient experienced a pleasant stupidity, declined food, and possessed no control over co-ordination, and, after one or two efforts, could not be induced to try to walk. Examination of the knee reflex was negative, excepting when the patient was caused to divert her mind to something else, and then only a very slight reflex was found to be present. Some ten days were required for her to regain her co-ordinating powers, at the end of which time the knee reflex was found to be normal. (Reported in the *Kansas City Medical Index*, August, 1891.)

CASE III.—A man, aged sixty-nine years, suffering from recurrent mania. Some ten days have elapsed since this attack came on. Before administering any medicine whatever, I demonstrated in the presence of the house surgeon, Dr. Thrush, that the deep reflexes were exaggerated. Friends state that the patient has not slept to amount to anything for twenty-seven nights; gave him thirty-five grains of sulphonal and he slept all night. The same dose was continued for four or five nights, when he developed inco-ordination till he walked with uncertainty, and would fall if not very careful. The dose was then reduced according to symptoms, varying from twenty to thirty grains for about fifteen days. During this time he slept well every night, and finally got to sleeping some during the day. I now examined his reflexes in the presence of Dr. Thrush and Dr. Willis P. King, and found them to be entirely absent. Diverting the patient's mind, causing him to close his eyes and pull on his hands, would not cause the reflex to return. After the discontinuation of the sulphonal for five days, his reflexes returned to their former condition, with entire recovery from his inco-ordination.

CASE IV.—This was a case of profound insomnia, which condition had been present for more than a year, and the patient was referred to me by Dr. Frick. The knee reflexes were exaggerated and their condition was noted. After the patient had taken twenty-five-grain doses of sulphonal for four successive evenings, inco-ordination appeared with reduction of the excessive reflex to considerably below normal.

Now, the point to which I wish to call attention is the loss of reflex after large or continued doses of sulphonal, and also to ask upon what hypothesis are we to account for this change? I regret to say that I have neglected in each case to examine the peripheral sensory condition.

Without a question there is a close connection between this loss of reflex and the inco-ordination, for in no case have I seen any change in the reflex until after symptoms of inco-ordination were manifest.

The only mention of a case in which the reflexes have been affected is in the *Satellite* for December, 1891, where a fifteen-year-old boy had taken a hundred grammes (over three ounces) of finely pulverized sulphonal, which he washed down with a large quantity of water. He walked in the open air for three quarters of an hour, after which he could give no account of himself, and in six hours was found unconscious. His temperature was 96° F.; pulse, 100, small but regular. Second day, sleeping quietly, face

slightly suffused, respiration quiet (18) and deep; pulse, 96 and extremely unsteady; reflexes uncertain, excepting the corneal reflex being distinct. Pupils reacted to light. Shaking, pricking of face, hands, and feet produced no effect except distinct widening of pupils. On the third and fourth days he slept soundly, reacting better to irritants without awakening. The subnormal temperature of 96° F. rose to 101.3° F. on the fourth day; fell again to normal, then rising to 100.8° F., and then falling to normal, where it remained. On the fifth day his eyes opened repeatedly, but still entirely unconscious. Pupillary reaction sluggish. On the sixth day consciousness returned, and he imagined himself on a ship, probably due to the dizziness. He could not walk or stand without assistance.

Now, I have no knowledge of any record of abolished reflexes from the use of sulphonal, excepting this one mentioned, and it only states that the "reflexes were uncertain." From a standpoint of diagnosis, it is important to know if the loss of reflex be due to disease or the use of sulphonal before coming to be examined, as a prognosis based on the loss of reflex due to organic disease would be quite dissimilar to the same condition due to the use of sulphonal.

By accepting the reflex theory advanced by Gowers, and that sulphonal, as a hypnotic, acts upon the cells of the cerebral cortex, we can account for the absence of the reflex in these cases. Gowers infers that we have a restraining or inhibiting power over the reflexes situated in the corpora quadrigemina or optic thalami, as has been demonstrated to exist in the optic lobes of the frog. Again, these inhibiting centers are controlled by a power residing within the higher or motor cortical cerebral centers, providing they are in a healthy state of activity. Now, if from any cause these cortical cells are prevented from exerting their power of control over the center which inhibits the reflex, this center goes uncontrolled and holds our reflex in check—that is, abolishes it. This would seem the most lucid explanation, for certainly all cortical functions seem suspended when under excessive doses of sulphonal, especially when toxic manifestations exist. Time and again of late I have been able to diminish the reflex by continued full doses of sulphonal, and to allow it to appear again by diminishing the dose or discontinuing it entirely.

## THE EFFECTS OF ALTITUDE UPON THE MUCOUS MEMBRANES OF THE UPPER AIR PASSAGES.

WITH REPORT OF CASES.\*

By G. MELVILLE BLACK, M. D.,

DENVER, COL.,

EX-HOUSE SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, N. Y.;  
LECTURER ON DISEASES OF THE EYE, EAR, NOSE, AND THROAT  
IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO.

I HAVE observed that people coming to this altitude, of one mile above sea level, from about sea level, experience within a day or so after arrival more or less symptoms attributable to an irritable condition of the mucous membranes

lining the upper air passages, especially that portion lining the nasal cavities. This irritable condition may develop into an inflammation, usually of a mild form, but may be quite severe. They attribute this, in a large proportion of cases, to "having caught cold." That this may be the case I will not dispute, and which I will try and show further on acts as the exciting cause with the low atmospheric pressure as the predisposing cause.

Taking Denver as our objective point, we have an atmospheric pressure of twelve pounds to the square inch, whereas at sea level the atmospheric pressure is 14.98 pounds to the square inch, a difference of about three pounds. Let a person come here who has been raised under this latter pressure; his vaso-motor nerves have been receiving a certain amount of nervous force to maintain an equilibrium of the vascular supply of the mucous membranes of the upper air tract. We know that the amount of blood in the sinuses of the turbinated bodies is very variable, owing to various atmospheric and systemic causes, but, notwithstanding, the equilibrium, day in and day out, remains about the same. This individual steps suddenly into this altitude and is maintained by an atmospheric pressure of three pounds less than that he has been accustomed to. What is the result? There is a greater amount of stimulus sent out to the vaso-motor inhibitory nerves, to arrest the vascular dilatation of the superficial capillary system of the whole body, and especially so to the mucous membranes of the upper air tract, inasmuch as the blood-vessels are much more exposed here than in cutaneous surfaces. This amount of nerve force is unusual and can only be kept up for a certain length of time, and finally gives way, the result being capillary dilatation, more or less over the whole body, but very slight, except in exposed mucous surfaces; and, inasmuch as the amount of nerve force required for cutaneous surfaces is very slight, as compared with exposed mucous surfaces, it is possible in a large percentage of cases for the extra amount of nerve force to be supplied to cutaneous surfaces without giving way. These individuals are particularly liable to catch cold, inasmuch as our days are warm and nights cold, and, by virtue of the fact of their depressed nervous vitality, a slight loss of bodily heat results in a much more marked relaxation of the vaso-motor control; and as the vessels of the upper air tract are already in an advanced stage of dilatation, we have the symptoms of a cold in the head setting in, a modified form of acute rhinitis with an accompanying inflammation of the mucous membrane down to the trachea; but the principal symptoms are referable to the nose. The patient complains of a sensation of fullness in the nasal region, extending up over the eyes, frontal headache, insomnia, some elevation of temperature—one to two degrees. Upon arising in the morning a tired, "used-up" feeling and a general feeling of exhaustion prevails all day. The nose discharges a thin watery fluid which may be quite profuse in the course of forty-eight hours; this continues unchanged for some days, then becomes somewhat thicker from exfoliation of epithelial cells, but does not become purulent at any time, as a rule. Resolution gradually sets in, beginning usually about the tenth day; the patient begins to feel very much better at this time, but is not free from some of the promi-

\* Read before the Denver and Arapahoe County Medical Society, January 12, 1892.

ment symptoms until about the twentieth day. The nose remains considerably "stopped up," however, after all the acute symptoms have subsided. The system is now becoming more accustomed to its new environments, and is able to supply more vaso-motor nerve force, but the least imprudence in exposure is liable to set our patient back. I do not mean to say that every one who comes to Colorado has to undergo this ordeal, but a large number do, and these cases are subjects who have been more or less troubled with catarrh for some years.

The nose, as we know, secretes about one pint of fluid in twenty-four hours, which is taken up by the inspired air. The amount of moisture required by this air depends upon how much water it is holding in suspension. The humidity at Denver will average about forty-nine per cent., whereas the average humidity in our Eastern States will be from eighty to ninety per cent. The amount of fluid secreted by a normal mucous membrane in Colorado I don't think has ever been estimated, but, if a pint is secreted in New York in twenty-four hours, the nasal mucous membrane in Colorado will have to do almost double duty to provide the air with the same amount of moisture. This additional activity undoubtedly brings about changes by virtue of this fact. The mucous membrane covering the turbinated bodies undergoes a true hypertrophy, and the vascular sinuses are constantly dilated to supply sufficient serum for the additional osmosis required. This finally results in a hyperplasia from the irritation caused by the approximation of turbinated bodies to the septum; the vacuum behind the point of contact increasing the vascular dilatation, connective tissue is thrown out between the vascular plexus until we have a true hyperplasia resulting. The patient finally gets some relief from the stenosis and accompanying symptoms by the contraction of this newly formed connective tissue, thereby reducing the size of the turbinated bodies somewhat and affording more air space. It is not my intention to go into the treatment of these conditions further than to say that in the acute condition a one-per-cent. solution of cocaine, with five grains antipyrine to the ounce, used as a spray every few hours, will afford much relief. In the resulting chronic condition local astringent applications have but little effect, but the judicious application of trichloroacetic acid to the turbinated bodies has worked admirably in my hands. Any nasal deformities should be corrected, such as removing with the nasal saw or trephine septal protuberances, straightening septal deviations, snaring out nasal polypi, etc. In short, first removing any previous existing nasal deformities, and, if the result is not adequate, touching the turbinated bodies with trichloroacetic acid. The following cases are examples of a number on my case-books:

CASE I.—C. F. R., male, aged nineteen. Been in Colorado about four years. Lived in Virginia formerly. Never any trouble with nose until he came to Colorado. Remembers of having "caught cold" the first day in Denver; says it troubled him for some time very much; thinks he has never got over it. Says his nose is stopped up a great deal of the time; can usually get some air through one side. Has to hawk every morning to expel a large quantity of mucus from throat, and does more or less of it all day. Thinks he is not so bad now as he was for

the first three years; had a good deal of headache then, very little now. An examination revealed both inferior turbinated bodies very much enlarged. Cocaine had the power to shrink them up about one half. Middle turbinated bodies were also found enlarged to a great extent. The septum was in fair condition—so much so that I did not meddle with it, but confined my treatment to applications of trichloroacetic acid, burning a long furrow at the lower surface of both inferior and middle turbinated bodies. I had to repeat the treatment once, burning in the oid tract. Gave him a spray composed of two ounces of benzoïnol and one drachm of eucalyptol. He has been relieved of all his symptoms.

CASE II.—Mr. T., aged thirty-five. Moved here from New York about three years ago. Thinks he used to have some catarrh in New York; never gave him much trouble, except when he had a cold. The first week he was in Denver he "caught cold"; thinks it was different from any cold he ever had, lasted longer, and made him feel worse. Nothing but a watery fluid came from nose. Says he "has never been able to breathe out of nose well since." To cut a long story short, he had typical hyperplasia of all the turbinated bodies, with quite a large spur projecting from lower part of left side of septum. This I removed, and reduced the size of turbinated bodies by use of trichloroacetic acid. He thinks he is in about the same condition now as when in New York.

#### REPORT OF A CASE OF TONIC SPASM OF ACCOMMODATION.\*

BY FRANCIS VALK, M. D.

IN one thousand cases of refraction on my note-books, I do not find a case of true tonic spasm of accommodation except the present case to be reported, and in a note by Professor D. B. St. John Roosa, in his translation of Schmidt-Rimpler's book, I find these words in reference to tonic spasm: "Certainly cases are very rare with us when atropine is to be used for months for spasm of the accommodation." The report, therefore, of the following case may be not only interesting, but also in showing some reason for a division of spasm of the ciliary muscle by Schmidt-Rimpler as tonic spasm of the accommodation and what he terms abnormal accommodative tension.

History as follows: Mr. C. N. A., aged forty-one, sent to me by Dr. Ford, Morristown, N. J. His family history perfectly good. In 1882 he was an Indian scout on the Western plains. He was brave and courageous and was in many dangerous places, having a rifle ball put through the rim of his hat, and at another time one struck the pommel of his saddle. After the shot through the hat, his left eye "felt badly" and he kept it tied up for a day or so. He states that his vision at this time was perfect, so that he could see at any distance. In 1884 he came East, and was writing in the editorial rooms of the *North American Review*. In that year he had an attack of paresis on the left side, with diplopia. He could not walk well without a cane; was deaf in the left ear, with dizzy sensation. These symptoms in time all passed away and his bodily health was good; some time after this, when his present troubles began, he bought a farm in the country and commenced living out there.

His friends state that he is extremely irritable, and will use

\* Read before the Ophthalmological Section of the New York Academy of Medicine, December 21, 1891.

profane language on the slightest provocation—a habit foreign to his usual temperament. He was found to be green blind completely, and partially so for red.

He can read very well, but feels tired and sleepy when doing so, while his distant vision is not good. When coming to the city the streets appear contracted like long lanes—evidently a narrowing of the field of vision, and, as he expresses it, “a dry contraction about the eyes.” This contraction feels like a band drawn around them. His vision at the first visit was as follows:

R. E. V. =  $\frac{2}{3}^{\circ}$ , w. —  $\frac{1}{3}^{\circ}$  =  $\frac{2}{3}^{\circ}$ . L. E. V. =  $\frac{2}{3}^{\circ}$ , w. —  $\frac{1}{2}^{\circ}$  =  $\frac{2}{3}^{\circ}$ .

He reads No. I J, at nine to nineteen inches, giving a region of accommodation, with diamond type, of about ten inches.

The examination by retinoscopy, using the plane mirror, shows myopic astigmatism in each eye, with the axis at  $180^{\circ}$  and  $45^{\circ}$ , respectively. I could not get any satisfactory examination with the ophthalmoscope, as the eyes were very sensitive to light, but the refraction appeared to be myopic. I at once ordered a four-grain solution of atropine to be used four times a day, and on his return in two days I found that his vision was  $\frac{2}{3}^{\circ}$  in each eye with —  $\frac{1}{6}^{\circ}$  combined with —  $\frac{1}{5}^{\circ}$  cylindric axis  $180^{\circ}$  in right and  $45^{\circ}$  left, but the vision was not steady.

Testing his extrinsic muscles at this time, I found a very peculiar effect, as with the apex of the prism over the right internus, with the candle placed at twenty feet, it would at once cause severe pain, and make him weep bitterly; while placing the apex over the left internus, he would laugh hysterically. Turning the prism around, and placing the apex over either of the externi, he would have a slight chill.

Considering that he was still under the effects of spasm of the ciliary muscle, I continued the atropine, and, not to weary you with details of the examination made at various times, I will state that the atropine was continuously used from February 21, 1891, the date of his first visit, till July 10, 1891, nearly five months, when the final examination revealed simple myopic astigmatism as follows:

R. E. V. =  $\frac{2}{3}^{\circ}$  +, w. —  $\frac{1}{4}^{\circ}$  c. ax.  $170^{\circ}$  =  $\frac{2}{3}^{\circ}$ . L. E. V. =  $\frac{2}{3}^{\circ}$  +, w. —  $\frac{1}{4}^{\circ}$  c. ax.  $80^{\circ}$  =  $\frac{2}{3}^{\circ}$ , and all other tests gave the same results, including the objective examination with Javel's ophthalmometer, which showed an astigmatism of less than 0.5 D. at the same axes. These glasses were ordered for continuous use at this time. I again tested the extrinsic muscles of the eyes, and found that the irritation as above noted with the prism test had entirely passed away, and that the interni can fuse the images with a prism of  $15^{\circ}$ , base outward, and the externi one of  $6^{\circ}$ , with the base inward. My last examination was made on November 20, 1891. He was perfectly comfortable, his vision normal, a good region of accommodation, and now uses his glasses only for reading.

During this course of treatment he was given strychnine in small doses for a month, and twice the temples were leeched.

In view of the history and result in this case, I think that we may consider tonic spasm of the accommodation exceedingly rare, and though I have seen those cases that may be classed as clonic, and in which we find spasm of the ciliary muscle taking place when the eyes are used for any distances, yet, as a rule, simple spasm of the accommodation or abnormal accommodative tension entirely disappears when the eye is examined with the ophthalmoscope and the true state of refraction is revealed, being either emmetropic, hypermetropic, or myopic. If, then, I should define the condition as it exists in the above case; the circular fibers of the ciliary muscle are in a state of continued contraction, producing a condition of accommoda-

tive myopia with an increase in the refractive power of the dioptric apparatus. This condition was constant and was, no doubt, the cause of the many peculiar reflex symptoms shown in this case. There is no pathological condition existing in this spasm, and the only objective symptom is the apparent myopia that does not agree with the usual tests for this myopic condition of refraction; and it is only by the ophthalmoscopic tests that we can differentiate that of true spasm. Hence, in the examination, when we compare the two conditions of tonic spasm and abnormal tension in both, we find the distant vision reduced; that it will be improved by concave glasses, but not up to that point usually observed in simple myopia of the same degree. That we have the same advancement of the near point, or, in other words, the near point is brought closer to the eyes; that in both cases the examination by retinoscopy will show myopia, giving reversed movements of the retinal reflex with the plane mirror. But that we will find our crucial test in the examination with the ophthalmoscope, as in simple spasm or abnormal accommodative tension, the apparent myopia will now disappear; for I believe the eye is unable to exercise its accommodative power and remains at rest when the ophthalmoscope is brought very close to it. While if we have this condition of true spasm, even with the ophthalmoscope, the refraction appears myopic. And yet the refraction with glasses does not agree with that usually found in simple myopia.

As regards the cause of true spasm of the accommodation, I can only suggest eye-strain as in the above case. I think that it was produced by the radical change in the use of the eyes from that of the Plains to the editorial rooms—in fact, from a condition of almost constant rest for the ciliary muscle to one of continuous work, until the stimulation became so great that there was no relaxation or rest at any time.

Again, as another possible cause, we have the peculiar axes of the weak minus cylindrics, being at  $170^{\circ}$  in the right eye and  $80^{\circ}$  in the left.

I think this condition might produce a certain amount of irritation in the ciliary muscle, ending in spasm.

Another point to which I would call your attention in this case is the peculiar effect produced upon the patient when the extrinsic muscles of the eyes are tested with prisms. You will see from his history that it was impossible to place a prism before his eyes with the base either in or out, as they would at once cause those peculiar seeming hysterical symptoms—crying or laughing if the base is placed outward, and a slight chill with the base inward; but these symptoms entirely disappeared after complete relaxation of the accommodation, when the balance of the muscular power was restored, giving over  $15^{\circ}$  for adduction and nearly  $6^{\circ}$  for abduction.

As regards the treatment of these cases, I do not think that I can suggest anything new. We must continue the use of atropine until the accommodation is completely relaxed, and this condition I find when all the examinations, both objective and subjective, agree in all particulars—in other words, when the ophthalmoscope, retinoscopy, and the test by glasses will give the same results—and not till

then should we stop the use of the mydriatic, even though the treatment must necessarily extend over several months.

In conclusion, I wish to report the following case that has some similar features: Clare B. was sent to my clinic at the Post-graduate Hospital by Professor Dana for examination of the eyes; her mother stated she was suffering from slight epileptoid attacks, having several during the day and night, generally commencing in the calf of the leg, and the medicine she had been taking seemed to have no effect in reducing their frequency. On examination, her vision was normal, with minus cylindric glasses of 2 D. axis 180° each eye. But as the other examinations did not agree with this, and suspecting tonic spasm, I ordered a four-grain solution of atropine to be dropped into the eyes four times a day, and after the accommodation was completely paralyzed, her vision now was found to be normal with convex cylindrical glasses of 1 D. axis 90° in each eye, and the convulsions were rapidly stopping, becoming less frequent, though all medical treatment was suspended at the time the atropine was ordered.

After the last examination she was ordered to wear the convex cylinders constantly and the atropine stopped, when we found the convulsions returning and the vision reduced. During the last two months she has been constantly under the effects of atropine, her vision is normal with the glasses, and has not had any return of the convulsions since November 18th.

Since the foregoing was written, Dr. George M. Gould, of Philadelphia, has mentioned a very similar case in his statistics of refraction. I report the history of these two cases, hoping they will be interesting to the members of the Section, because the effects of the use of the atropine seemed to be so marked and the relief and final results so interesting to me, and because I have never met any similar cases among the large number I have examined in private and clinical work.

**The New York Academy of Medicine.**—The programme for the meeting of Thursday evening, the 7th inst., announced the following papers: An Efficient Means of controlling Hemorrhage after Suprapubic Prostatectomy, by Dr. E. L. Keyes; A Peculiar Case of Renal Hemorrhage, etc., with some Observations upon the Value of Cystoscopy in the Diagnosis of Renal Diseases, by Dr. Samuel Alexander; and Some Results of "Withdrawal," by Dr. L. Bolton Bangs.

At the next meeting of the Section in General Surgery, on Monday evening, the 11th inst., Dr. C. A. Powers will read a paper entitled A Case of Spina Bifida in an Adult; Removal of the Tumor; Cure, and Dr. Robert F. Weir will read one on A Unique Derangement of the Knee Joint demanding Surgical Interference.

At the next meeting of the Section in Pædiatry, on Thursday evening, the 14th inst., Dr. J. E. Kelly will read a paper entitled The Practitioner's Anatomy of the Respiratory Passages as applied to Intubation, Laryngotomy, Tracheotomy (high and low), and Bronchotomy.

At the next meeting of the Section in Orthopædic Surgery, on Friday evening, the 15th inst., Dr. V. P. Gibney will read a paper on The Indications for Operative Interference in Orthopædic Surgery.

**The Harlem Hospital.**—The Commissioners of Public Charities and Correction have appointed Dr. S. T. Armstrong a member of the medical board. Dr. Armstrong has had an extensive professional experience in his ten years' service as a medical officer in the Marine-Hospital Service, and will render efficient service in this new field.

THE  
NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, APRIL 9, 1892.

ATHENIAN HOSPITALS.

In a letter from Athens, Greece, Dr. Frederick Peterson, of New York, writes that the general hospital in that city, known as the Evangelismos, is quite equal to any institution of the kind in the world in its structure, arrangements, care of patients, neatness, cleanliness, and attention to the latest medical and surgical details; records are religiously kept by the internes, who are students or graduates of the medical department of the Athenian University; and work of a high order is done in its laboratory, which is provided with every appliance needed for chemical, bacteriological, and pathological investigation. The operating-room for general surgery and the laparotomy room are models of cleanliness and attention to antiseptics, and are perfectly equipped with every surgical requisite. The various means of treatment of typhoid fever—medicinal, stimulant, and hydrotherapeutic—are being carefully tried in order to determine their relative merits. There seemed to Dr. Peterson to be an unusual number of such cases among the sixty or seventy inmates of the hospital at the time of his visit. Driving out of town, past the site of the ancient grove of Plato and Soerates, along the "Sacred Way" to Eleusis, one reaches in half an hour the new Phrenocomio, or lunatic asylum, of Athens. For years Greece had had but one asylum, situated at some distance on the island of Corfu, and patients of the better classes were sent to Italy, France, or Germany, or elsewhere; but a few years ago a wealthy Athenian gave a million francs toward an establishment of this kind to be located near the city, so this site of several hundred acres of land on a slope of the Parnes hills, overlooking the Bay of Salamis, and with Hymettus, Pentelikon, and the Acropolis looming up in the foreground, was selected. At present, says Dr. Peterson, there are a hundred patients in five or six pavilions. Most of the patients are private, but all classes, including paupers, are accommodated, and new pavilions are being added continually. One of the features of the asylum is a hydrotherapeutic establishment with every known form of douche and bath apparatus, more complete than Dr. Peterson remembers ever to have observed elsewhere, although he has visited most of the asylums and hospitals of Europe in former years. This hydrotherapeutic installation is the work of an Italian firm in Bologna.

The number of cases of general paralysis—fourteen—was noticeably large. Alcoholic insanity, strange to say, is exceedingly uncommon, although many Grecian wines are well known to be of fiery quality. Dr. Cirigotti, the medical superintendent, said he believed the cause of this to lie in a certain peculiarity of the wines drunk by the people in general—viz.:

the large quantity of resin of the Aleppo pine that they contain. The flavor of pine resin is so strong that few foreigners care to essay a second mouthful after the disgust and surprise aroused by the first. The Greeks drink the resined wines by preference. Whether Dr. Cirigotti is correct in ascribing to pine resin properties antagonistic to the poisonous effects of alcohol, Dr. Peterson does not presume to say, but the matter, he says, may merit some investigation, for the almost complete absence of alcoholic insanity in an intemperate people is a singular circumstance.

#### PYOCTANIN IN DISEASES OF THE EYE.

STILLING, of Strassburg, the apostle of this coal-tar "pus-killer," has had some of his allegations confirmed and some of the strongest of them denied, and new uses of it have been proposed about which he was in ignorance. A short paper by Dr. Herbert Harlan, in the *Transactions of the Medical and Chirurgical Faculty of Maryland* for 1891, illustrates this statement in an interesting way. First, it confirms the usefulness of pyoctanin in ulcer of the cornea; secondly, in purulent ophthalmia the drug is shown to be well-nigh useless or, at least, less efficient than other older medicaments; and, thirdly, new uses with gratifying results have been developed in regard to oyster-shuckers' keratitis and to phtheiriiasis palpebrarum.

In and about Baltimore the corneal lesions of oyster-openers are well known, and they are commonly described as a form of keratitis. They are of the nature of corneal ulcers, and are caused by small particles of shell or slime impinging upon the eye in the process of shucking oysters. The appearance of the eye and the limited *locale* of the disease point to a causation by some peculiar micro-organism not yet discovered. These cases of oysterman's keratitis are not readily cured, although eserine in solution has done well in the practice of the author of the paper. Latterly he has made use of pyoctanin in twenty of these cases, and in every case with marked benefit. The method of treatment is usually to drop into the eye a solution of cocaine, and then after a moment rub the ulcer with a pencil of yellow pyoctanin. In the milder cases one application has sufficed; in one very severe case, with an ulcer occupying a quarter of the corneal area, a cure was obtained at the end of ten days, a slight opacity remaining. One effect of the pencil was to stain the diseased spot bright yellow. In three cases of mucocele the injection of blue-pyoctanin solution seemed to be more promptly remedial than the use of any other astringent or antiseptic solution before employed by the author.

On the very day when the author obtained his first supply of the drug there came to him a boy of fifteen having the eyelashes of the right eye infested with lice (*pediculi pubis*). Now, these cases are not very common in this country, and are interesting therapeutically. The patient complained of an intense itching and irritation of the eyes. Close inspection showed a few lice moving about on the lashes and a vast number of eggs firmly agglutinated to the lashes. It is very difficult to destroy these eggs, or to prevent their development, under the usual treatment with red-precipitate or yellow-oxide-of-mer-

cury ointment. The destruction of the living lice is effected by either of these ointments, and, if the latter is persistently used for a week or two, the newer crops of lice are killed as they are successively hatched out; the unguents, however, do not penetrate the glue-like covering of the eggs. In the case of this boy, Dr. Harlan at once proceeded to make trial of a solution of blue pyoctanin, one part to a thousand. The living parasites were stained blue and were killed; nearly all the eggs took the stain, and none of them subsequently, during the period of two weeks for which the boy was under observation, were developed. Two applications were all that were made, the second application having been made because a few of the eggs had not taken the stain so thoroughly as the others on the first application, which, however, was probably fatal to the entire brood.

Regarding the use of pyoctanin in some forms of intra-ocular trouble, Dr. Harlan has had some favorable results, and he purposes to use the remedy in other cases.

#### MINOR PARAGRAPHS.

##### ALBUMINOUS PERIOSTITIS.

ACCORDING to the *Lancet* for March 12th, Dr. Dzierzawski has published an article on the "periostitis albuminosa" of Poncet, Terrier, and Lannelongue, of which he has collected twenty-seven cases besides one of his own. It is characterized by a clear, tenacious exudation from the periosteum that resembles synovial fluid or the white of an egg. The author does not believe it a disease *sui generis*, as Nicaise, Riedinger, Albert, and Duplay do, but thinks it is comparable to those cases of contagious osteomyelitis in which a clear fluid exudation is formed owing to a low type of inflammation, or to those tubercular cases in which there is infiltration or cold abscess. This view coincides with that of Schlange, who, however, ascribes the small number of pus-corpuscles to their deficient formation in consequence of the weakness of inflammation; and Garré supposes that there is secondary liquefaction of these bodies by the serous exudation. These theories the author does not believe necessary, as under certain conditions the periosteum may give rise to an exudation containing mucus, and he proposes that the disease be called "non-purulent osteo-periostitis."

##### DYSPNEA AFTER TEA-DRINKING.

MR. JONATHAN HUTCHINSON, in the January issue of the *Archives of Surgery*, describes a case of alarming attacks of dyspnea that were probably due to tea-drinking. The patient was a rather delicate man, of nervous temperament, and there was a suspicion of gouty heredity. The attacks occurred after breakfast, at which he drank tea freely, the meal being brought to him while he was yet in bed. During the attacks he had a corpse-like pallor, and seemed quite unable to take a respiration, on account of a pain like that of angina pectoris caused by the effort. The pain was referred to the epigastrium and lower part of the chest, rather than to the shoulder. Inspiration was accompanied with the greatest pain. The pulse was feeble during the time of the attack, and the patient could speak only in a whisper. The duration of the attacks was about an hour. An injection of morphine terminated the seizure quite promptly on two or more occasions. A careful thoracic examination, made by Dr. Gowers, resulted for the most part negatively. At any rate, no organic

affection was discovered that could explain the difficulty. The man was not a user of tobacco, but would imbibe tea freely, and this was sometimes followed by flatulence and a feeling of distention of the stomach. An over-indulgence in tea, especially with little or no food taken at the same time, will in some persons produce a sense of constriction behind the sternum, with some feeling of dyspnoea. In the case of a medical man who partook of tea of unaccustomed strength, and without eating any food, a distressing attack of dyspnoea occurred which lasted over thirty minutes. The recurrence of somewhat similar attacks having followed other indiscretions of tea-drinking on subsequent occasions, the mind of that physician became strongly impressed with the agency of strong tea in causing such attacks; so much so that for a long time he never ventured to drink tea except in his own home, where he knew its strength and quality. Mr. Hutchinson states that the painful attacks of the patient first above referred to bring to mind very distinctly those from which John Hunter suffered, and which he himself so graphically described.

#### A SUCCESSFUL LAPAROTOMY IN THE SEVENTEENTH CENTURY.

The following note in the *Diary of John Evelyn* would indicate that our professional brethren of two hundred and fifty years ago were not very far behind us in the matter of abdominal section for foreign bodies. It is dated Leyden, August 19, 1641, and reads: "Among a great variety of other things I was shewn the knife newly taken out of a drunken Dutchman's guts by an incision in his side after it had slipped from his fingers into his stomach. The pictures of the surgeon and his patient, both living, were there."

#### THE COLLEGE OF PHYSICIANS AND SURGEONS, OF CHICAGO.

We have received the first decennial catalogue and the announcement for the coming college year. Both documents show abundant evidence that the institution is decidedly progressive in its means of teaching and in its requirements for entrance and for graduation. It may be said, indeed, to be in the first rank of American medical colleges.

#### ITEMS, ETC.

The **Medical Association of Georgia** will hold its forty-third annual meeting in Columbus on the 20th, 21st, and 22d inst., under the presidency of Dr. G. W. Mulligan, of Washington. In addition to the president's address, the preliminary programme announces the following papers: Cough—Some of its Causes and Treatment, by Dr. C. D. Roy, of Atlanta; So-called Typho-malarial Fever, by Dr. W. P. Williams, of Waycross; Preliminary Observation on the Behavior of Iodine in the Presence of Camphor, Menthol, Thymol, etc., by Dr. R. J. Nunn, of Savannah; Some Observations upon Cataract Operations and After-treatment, by Dr. A. W. Calloun, of Atlanta; Remittent Fever, by Dr. A. C. Blain, of Brunswick; Extirpation of the Rectum for Carcinoma, by Dr. J. McF. Gaston, of Atlanta; Some of the Fads and Fancies of the Medical Profession, by Dr. J. C. LeHardy, of Savannah; The Treatment of Pneumonia, with Report of Cases, by Dr. H. Perdne, of Barnesville; How shall we manage the Uterus after Abortion? by Dr. K. P. Moore, of Macon; Plaster of Paris in Surgery, by Dr. W. F. Westmoreland, of Atlanta; Report of Surgical Cases from my Note-book, by Dr. J. B. Hinkle, of Americus; What is Gynaecology? by Dr. R. R. Kinne, of Atlanta; A Case of Ovarian Cysts, by Dr. J. M. Spence, of Waresboro; Some Remarks on Tonsil Excisions, with the Presentation and Description of a New Instrument, by Dr. A. G. Hobbs, of Atlanta; How to best conduct Labor to prevent Injuries to the Os Uteri and Perinaeum, by Dr.

A. W. Griggs, of West Point; Gunshot Wounds of the Eye—Unusual Results, by Dr. G. A. Wilcox, of Augusta; The Treatment of Abortion and Some of the Complications, by Dr. Walter A. Crow, of Atlanta; Report of a Case of Catalepsy and its Treatment, by Dr. A. Sydney Johnson, of Bowman; Typhilitis and the Report of a Case, by Dr. S. M. Mathews, of Quitman; The Relations and Dependencies existing between the Specialist and the General Practitioner of Medicine and Surgery, by Dr. J. W. Griggs, of West Point; The Relation between Skin Diseases and the General Health, by Dr. M. B. Hutchins, of Atlanta; The Treatment of Hemorrhoids by Carbolic-acid Injection, by Dr. J. W. Hallum, of Carrollton; Hemeralopia, or Night-Blindness, by Dr. S. Latimer Phillips, of Savannah; A Combination of Carbolic Acid and Camphor as an Antiseptic, by Dr. W. Perrin Nicolson, of Atlanta; Chorea, by Dr. Hugh Hagan, of Atlanta; Antiseptic Surgery, by Dr. Ralph E. Smith, of Atlanta; Radical Surgery the Best Surgery in the Treatment of Extensive Lacerated and Contused Wounds of the Extremities, by Dr. E. H. Richardson, of Atlanta; Typho-malarial Fever, by Dr. J. W. Duncan, of Atlanta; The Action of Fibroid Tumors after the Menopause, by Dr. Virgil O. Hardon, of Atlanta; Intestinal Obstructions—their Varieties, Diagnosis, and Treatment, by Dr. J. B. Hinkle, of Americus; A Report of Perineal Sections for Stricture, Stone in the Bladder, and Cystitis, by Dr. Floyd W. McRae, of Atlanta; Suprapubic Lithotomy, with a Report of Cases, by Dr. W. S. Elkin, of Atlanta; and Typhilitis, by Dr. William O'Daniel, of Bullard.

The late **Dr. D. Hayes Agnew**.—The secretary of the College of Physicians of Philadelphia, Dr. Charles W. Dulles, has sent us the text of a minute adopted by the college on March 24th. It reads as follows:

The death of Dr. D. Hayes Agnew, recently president of the college, in the seventy-fourth year of his age, and after a life crowned with honor and usefulness, calls for an expression of the sense entertained by the college of the gravity of the loss which it suffers, in common with the profession he adorned, the charitable institutions he served, and the community in which his skill did so much to lessen suffering and death.

He began his professional life with no adventitious aids; yet, by incessant industry, indomitable perseverance, and singleness of purpose, he attained to its highest rank. No temptation distracted his attention from the goal of his life: neither extraneous science, nor general literature, nor the allurements of art, nor the pleasures of society.

The undivided strength of his mind and his affections were devoted to enlarging the domain of surgery, not only in its operative methods, which he always subordinated to the welfare of his patients, but also in preparing for his profession a literary monument that might speak for him when his voice should be no longer heard.

His minute acquaintance with anatomy and his ambidextrous skill enabled him to perform, with ease to himself and safety to his patients, operations which less accomplished surgeons hesitated to undertake.

He possessed a certain magnetism of manner, quite independent of formality, that evidently proceeded from the heart and drew all hearts to himself. Never frivolous, but always cheerful, he was dignified, grave, and earnest, making all who heard him as a teacher and speaker, or in familiar intercourse, recognize in him, above all other things, the upright man. For he possessed eloquence of conviction and the force of absolute honesty in all his statements, and thereby drew to himself as enthusiastic admirers and disciples the successive classes of students whom he taught.

The college, desiring to show respect for the purity, uprightness, unselfishness, and modesty of Dr. Agnew's character, its admiration for the noble example of life, and its sense of the value of his contributions to the science and art of surgery, directs that this minute shall be duly recorded, and a copy of it, signed by the president and secretary, be conveyed to Dr. Agnew's family. Also, that the college will attend the funeral in a body, and that the president be requested to appoint a fellow to prepare a memoir of our late colleague.

The **American Academy of Medicine** will hold its seventeenth annual meeting in Detroit on Saturday, June 4th, and Monday, June 6th. In the preliminary programme we find the following titles: Essentials and Non-essentials in Medical Education, the address of the retiring

president, Dr. P. S. Conner, of Cincinnati; The Value of the General Preparatory Training afforded by the College as compared with the Special Preparatory Work suggested by the Medical School in the Preliminary Education of the Physician, by Dr. T. F. Moses, of Urbana, O.; Does a Classical Course enable a Student to shorten the Period of Professional Study? by Dr. V. C. Vaughan, of Ann Arbor, Mich.; The Value of a Collegiate Degree as an Evidence of Fitness for the Study of Medicine, by Dr. L. H. Mettler, of Chicago; The Value of Academical Training Preparatory to the Study of Medicine, by Dr. H. B. Allyn, of Philadelphia, Dr. W. D. Bidwell, of Washington, and Dr. Elbert Wing, of Chicago; The Newer Medical Education in the United States, by Dr. W. J. Herdman, of Ann Arbor, Dr. Charles Jewett, of Brooklyn, and Dr. Elbert Wing, of Chicago; and a paper on some phase of the State supervision of the practice of medicine, by Perry H. Millard, of St. Paul.

**Meetings of State Medical Societies for the Month of May.**—Kentucky State Medical Society, 3d, Louisville; Kansas Medical Society, 3d, Fort Scott; Ohio State Medical Society, 3d, Cincinnati; State Medical Society of Wisconsin, 4th, Milwaukee; Michigan State Medical Society, 5th, Flint; Nebraska State Medical Society, 10th, Omaha; Indiana State Medical Society, 12th, Indianapolis; Missouri State Medical Society, 17th, Pertle Springs; Illinois State Medical Society, 17th, Vandalia; Pennsylvania State Medical Society, 17th, Harrisburg; Iowa State Medical Society, 18th, Des Moines; Connecticut Medical Society, 24th, New Haven; North Carolina State Medical Society, 24th, Wilmington.

**The Association of Military Surgeons of the National Guard of the United States** will hold its second annual meeting in St. Louis on the 19th, 20th, and 21st inst., under the presidency of Dr. N. Senn. Information in regard to the meeting may be obtained from Colonel E. Chancellor, of No. 515 Olive Street, St. Louis.

**The Mississippi Valley Medical Association.**—Members who wish to go as delegates to the meeting of the American Medical Association at Detroit are requested by the secretary, Dr. E. S. McKee, of No. 57 West Seventh Street, Cincinnati, to send their names to him.

**Change of Address.**—Dr. Burdette P. Craig, to No. 258 Montgomery Street, Jersey City.

**Marine-Hospital Service.**—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the four weeks ending March 26, 1892:*

BAILHACHE, P. H., Surgeon. To inspect unseviceable property at Port Townsend, Wash., March 9, 1892. Detailed as member of Board for Physical Examination of Officers of the Revenue-Marine Service. March 26, 1892.

PURVIANCE, GEORGE, Surgeon. Ordered to Washington for temporary duty. March 5, 1892.

AUSTIN, H. W., Surgeon. To inspect service at New Orleans, Savannah, and Charleston, and the Gulf and South Atlantic Quarantine Stations. March 3, 1892.

IRWIN, FAIRFAX, Surgeon. Detailed as Medical Inspector of Immigrants, port of Boston, Mass. March 3, 1892.

CARMICHAEL, D. A., Passed Assistant Surgeon. To inspect the San Francisco Quarantine Station. March 7, 1892.

WHITE, J. H., Passed Assistant Surgeon. Ordered to South Atlantic Quarantine for temporary duty. March 26, 1892.

KINYOUN, J. J., Passed Assistant Surgeon. To proceed to New York on special duty. March 7, 1892.

PERRY, T. B., Passed Assistant Surgeon. Granted leave of absence for thirty days. March 1 and 14, 1892.

GUITÉRAS, G. M., Assistant Surgeon. Ordered to examination for promotion. March 23, 1892.

BROWN, B. W., Assistant Surgeon. Assigned to temporary duty at San Francisco Quarantine. March 14, 1892.

EAGER, J. M., Assistant Surgeon. Granted leave of absence for thirty days. March 1, 1892.

DECKER, C. E., Assistant Surgeon. Detailed as Recorder, Board for Physical Examination of Officers of the Revenue-Marine Service. March 26, 1892.

#### Promotion.

COBB, J. O., Passed Assistant Surgeon. Commissioned by the President as Passed Assistant Surgeon. March 23, 1892.

#### Society Meetings for the Coming Week:

MONDAY, *April 11th*: New York Academy of Medicine (Section in General Surgery); New York Ophthalmological Society (private); Lenox Medical and Surgical Society (private); New York Medico-historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Boston Society for Medical Improvement; Gynecological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

TUESDAY, *April 12th*: Medical Association of the State of Alabama (first day—Montgomery); Medical Society of the State of Tennessee (first day—Knoxville); New York Medical Union (private); Kings County, N. Y., Medical Association; Medical Societies of the Counties of Jefferson (quarterly—Watertown), Oneida (quarterly—Utica), Ontario (quarterly), and Tioga (quarterly—Owego), N. Y.; Newark and Trenton (private), N. J., Medical Associations; Bergen (annual—Hackensack) and Cumberland (annual), N. J., County Medical Societies; Fairfield, Conn., County Medical Association (annual); Baltimore Gynecological and Obstetrical Society.

WEDNESDAY, *April 13th*: Medical Association of the State of Alabama (second day); Medical Society of the State of Tennessee (second day); New York Surgical Society; New York Pathological Society; Metropolitan Medical Society (private); American Microscopical Society of the City of New York; Tri-States Medical Association (Port Jervis, N. Y.); Medical Society of the County of Albany, N. Y.; Pittsfield, Mass., Medical Association (private); Philadelphia County Medical Society; Kansas City, Mo., Ophthalmological and Otolological Society.

THURSDAY, *April 14th*: Medical Association of the State of Alabama (third day); Medical Society of the State of Tennessee (third day); New York Academy of Medicine (Section in Pediatrics); New York Laryngological Society; Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; Medical Societies of the Counties of Cayuga and Fulton (quarterly), N. Y.; South Boston, Mass., Medical Club (private); New London, Conn., County Medical Society (annual); Pathological Society of Philadelphia.

FRIDAY, *April 15th*: Medical Association of the State of Alabama (fourth day); New York Academy of Medicine (Section in Orthopedic Surgery); Baltimore Clinical Society; Chicago Gynecological Society.

SATURDAY, *April 16th*: Clinical Society of the New York Post-graduate Medical School and Hospital.

#### Answers to Correspondents:

No. 379.—An examination is required. For particulars, address the Board of Regents of the University of the State of New York, Albany.

## Letters to the Editor.

### THE PRESERVATION OF HYPODERMIC-SYRINGE TUBES.

GREENVILLE, PLUMAS COUNTY, CALIFORNIA, *March 23, 1892.*

*To the Editor of the New York Medical Journal:*

SIR: Apropos of Dr. T. A. Lancaster's letter upon the Preservation of Hypodermic Needles with Unguentum Petrolei, I would suggest the use of a small collapsible ointment-tube containing half a drachm of the unguent, the screw thread retaining its cap having a similar gauge to that of the syringe, and the cleansed needle to be screwed on to the tube, pressure filling the needle with the lubricant. The manœuvre would be simple, and the tube would take up little space in a case.

G. WILLIS, L. R. C. P. Edin., L. R. C. S. Edin.

## Proceedings of Societies.

### NEW YORK NEUROLOGICAL SOCIETY.

Meeting of March 1, 1892.

The President, Dr. L. C. GRAY, in the Chair.

**Hysteria in a Child.**—Dr. W. M. LESZYNSKY presented a patient, a young girl, whom he said he had brought to demonstrate that we did have in this country cases of hysteria in children. She was, he said, only thirteen years of age. Two years and a half ago, after fright from a dream, the hysterical symptoms had manifested themselves in paroxysms of laughing and crying. In 1891 she had commenced to menstruate, and had then begun to have convulsive seizures, which had been usually worse at the menstrual periods. She had passed through conditions of pre motor aphasia, and at the present time there were attacks of mutism lasting for a week or more. She also now had convulsions lasting sometimes many minutes, and at other times for hours. There were now developed hysterogenic zones over various parts of her body. She had visual hallucinations, and occasionally maniacal attacks and movements of rotation and of combined rotation and retropulsion. Her visual fields had been contracted. Lately there was a transient hemiplegia. There were no sensory disturbances. Knee-jerk was present, but only slightly marked. There was no history of onanism, and none of ovarian trouble, and the general health of the child was good. This was the patient he had referred to on a previous occasion as becoming worse after hypnotism. The speaker then touched the patient upon the head in one of the alleged hysterogenic zones, when a convulsive seizure promptly occurred.

**Morvan's Disease.**—Dr. B. SACHS presented a patient and gave the history of his case. (To be published.)

Dr. M. A. STARR said that, in a late discussion on syringomyelia, it had been stated that no case had come to autopsy in which a diagnosis had been made during life. He had lately received photographs of four spinal cords from cases from the Salpêtrière in which the diagnosis had been so made.

Dr. C. L. DANA said he was far from being convinced that there was at present anything the matter with the patient's spinal cord. He had seen a similar condition which had been really one of peripheral neuritis. He thought it possible for Morvan's disease to exist as an independent trouble. The case before them was interesting and in many respects a connecting link, but he should hesitate in unreservedly accepting it as one of syringomyelia.

Dr. SACHS said that some improvement had taken place in the areas of sensory disturbance which would be hardly expected in a case of peripheral neuritis.

**The Diseases and Conditions to which the Rest Treatment is adapted.**—Dr. WHARTON SINKLER, of Philadelphia, read a paper with this title. He said the treatment indicated consisted mainly in absolute rest, over-feeding, passive exercise in the form of massage and electricity, isolation from friends and relations in hysterical and neurasthenic patients, and in other details. In placing a patient under treatment, no matter for what disorder, it must be made clear what the plan was, in order that such patient might assist the physician to a speedy result. The degree of rest which should be enforced might vary, but, as a rule, patients were permitted to do but little for themselves. They should remain constantly in bed, rising only to attend the calls of Nature, and even this was not always to be allowed. Usually the patient was rolled from the bed to a lounge or cot once a day during the airing or changing of the bed linen. Be-

yond this no exertion must be permitted, and everything must be undertaken by the nurse. Isolation was an important part of the system, and visitors and messages should be excluded. Massage, the toilet hour, the doctor's visit, the electricity, and the meals gave sufficient occupation. It was rarely possible to treat patients in their own home, no matter how isolated the patients might be. The moral effect of removal from home was frequently of an enormous benefit in cases of neurasthenia or hysteria. Massage was an essential element in the treatment, and one of its objects was to produce tissue waste in order to admit of a larger amount of food being given. Faradaic electricity should be used once daily for half to three quarters of an hour. After giving the conventional dietary list, the author said that, as a rule, at the end of six weeks the patient was allowed to sit up, lengthening the time gradually day by day. The judicious selection of a nurse with special qualifications was a *sine qua non*. Hysteria and neurasthenia were the diseases to which the rest treatment had been most extensively applied, and in which it gave the most satisfactory results. Some of the organic diseases of the cord, Pott's disease, acute myelitis, locomotor ataxia, spastic paraplegia, peripheral nerve troubles, migraine, certain brain troubles dependent upon malnutrition, such as melancholia and the insanities of exhaustion, had all been wonderfully helped by the rest treatment. Success had also attended the treatment of chorea, epilepsy, the opium habit, and alcoholism by this method. Gynecologists had also used it with benefit in uterine and ovarian diseases. Some very good results had been obtained by the plan in the treatment of Bright's disease. The relation of lithæmia to nervous diseases had of late attracted much attention. Many forms of nervous troubles, such as migraine and some neuralgias and certain forms of neurasthenias, were dependent upon the lithæmic diathesis. The best method of eliminating uric acid was by exercise and diet with an abundance of diluent drinks. The rest treatment was particularly adapted to the management of these cases. The speaker emphasized that Swedish movements should be used in combination with massage.

Dr. E. D. FISHER did not advocate the carrying out of the rest-cure principles too rigidly. He had seen a patient with nervous disease, sent to Philadelphia for the purpose of isolation from her family, make a very rapid retrograde march toward the grave. This had been noted in time to apply the remedy, which consisted in bringing her back to this city.

Dr. STARR said it was his custom to send his patients to Dr. Weir Mitchell. Possibly one half the benefit from the course arose directly from the hypnotic suggestion with which it was associated, and this could be better carried out in a special institution. He believed the rest treatment to be admirable and applicable to many cases, but not to all. It would be the more likely to succeed where mental suggestion was of direct benefit.

Dr. SACHS thought that in cases proper for such treatment it might be just as effective here as in Philadelphia. It was more satisfactory when used in its more modified forms. A goodly number of cases in females classed as hysterical were really hypochondriacal, and for these patients isolation with one attendant\* was not to be advocated.

Dr. G. W. JACOBY called attention to the very pronounced obesity which often ensued from the rest in bed.

Dr. S. B. LYON, alluding to the possible objection to manual massage by reason of the personal element, said that at one institution massage was effectively carried out by mechanical methods.

The PRESIDENT said that he had used the method for twelve years, and was willing to accord the genius of Dr. Mitchell all it deserved. Experience had not demonstrated the plan as uni-

versally efficient. In genuine hysteria, hysteria associated with malnutrition, emotional hysteria, cases of over-draft upon the physical capacity by work or other causes in which the disturbance was functional, not organic, he believed the treatment in most instances would be found invaluable, while in melancholia it was not so useful. The plan must always be modified to suit special requirements. He did not believe in the massage part of it. Patients became beautiful to look upon, but their muscular capacity amounted to nothing.

Dr. SINKLER thought that in Dr. Gray's cases massage could not have been given thoroughly; it was essential to the treatment as a whole, but should always be combined, if possible, with the Swedish movements.

## Book Notices.

*The Aetiology, Pathology, and Treatment of Diseases of the Hip Joint.* By ROBERT W. LOVETT, M. D., Out-patient Surgeon to the Boston City Hospital, etc. Boston: George H. Ellis, 1891. [Fiske Prize Fund Dissertation, No. 42.]

WHATEVER may be said of prize essays in general, and numerous objections have been urged regarding their utility, the trustees of the Fiske Fund of the Rhode Island Medical Society have manifested careful judgment in the selection of the essays to which they have awarded the prize in several years past.

In this volume the author has confined his discussion of the subject to the three topics prescribed by the trustees, dividing diseases of the hip joint into acute and chronic diseases and miscellaneous conditions. The first class includes acute arthritis and acute synovitis, both serous and purulent. The second class includes serous and purulent chronic synovitis, tubercular and gummatous chronic osteitis, arthritis deformans, Charcot's disease, malignant and other tumors affecting the joint, and loose bodies in the joint. The third class includes congenital dislocations and functional affections.

The author's presentation of the aetiology, pathology, and treatment of these varieties of hip-joint disease includes the latest data on the subject. In tubercular osteitis he believes that where injury causes the disease it must be assumed that tubercle bacilli were present in the circulation and were localized by the injury, though he believes that, as a rule, hip disease occurs only in those having an hereditary or acquired tendency to tuberculosis. In the treatment of the disease Knight's protection method and Hutchinson's physiological method are mentioned; while the author accepts Phelps's view that fixation *per se* does not produce ankylosis, still he thinks that method incomplete because it is almost impossible to obtain fixation unless the whole body is immobilized, and, further, that the absence of traction is an objection. His preference is for the long traction splint, with the routine use of crutches. He believes that excision is proper and necessary where mechanical treatment is not practicable and where, after careful and intelligent trial, it has failed.

In congenital dislocation of the hip joint Hoffa's operation is held to be still on trial, while mechanical measures and most methods of operative treatment have been useless.

The book is a comprehensive survey of the subject of hip diseases.

*Physical Diagnosis.* A Guide to Methods of Clinical Investigation. By G. A. GIBSON, M. D., D. Sc., F. R. C. P. Ed., Lecturer on the Principles and Practice of Medicine in the Edinburgh Medical School, etc., and WILLIAM RUSSELL, M. D.,

F. R. C. P. Ed., Pathologist to the Royal Infirmary of Edinburgh, etc. With Illustrations. New York: D. Appleton & Co., 1891. Pp. 367.

So many works on physical diagnosis have recently appeared that it would seem that there could be no room for more, but this work occupies a somewhat peculiar position, inasmuch as its scope is greater than that of a mere treatise on physical diagnosis. It might, rather, be entitled *A Condensed Manual of Clinical Diagnosis*, since in a concise manner the authors have given us chapters upon methods of examination; the temperature; the integumentary system; the respiratory system; the alimentary system, including the abdominal viscera; the urinary system; the nervous system; and examination of the eye, the ear, the larynx, and the naso-pharynx. All these subjects are treated by the authors in a clear, concise, and vigorous style, and with sufficient attention to details to satisfy the reader who simply wishes to learn certain definite facts in regard to the physical and clinical signs of diseases.

The chapters on the respiratory system and the circulatory system and on urinalysis may be mentioned as especially full, but all the chapters are good. The illustrations and diagrams are plentiful and handsomely executed, and the typographical appearance of the book is excellent. It can be recommended to those who desire a condensed treatise on physical and general clinical diagnosis.

*A Manual of Hypodermatic Medication: the Treatment of Disease by the Hypodermatic or Subcutaneous Method.* By ROBERTS BARTHOLOW, A. M., M. D., LL. D., Emeritus Professor of Materia Medica, General Therapeutics, and Hygiene in the Jefferson Medical College of Philadelphia, etc. Fifth Edition, revised and enlarged. Philadelphia: J. B. Lippincott Company, 1891.

THE present edition of this familiar work is larger by two hundred pages than its predecessor. In addition to the new remedies mentioned, many new observations upon the hypodermic use of older ones have been added. If the author has erred, it has been in speaking of too many remedies only to condemn them. Particular attention has been paid to the subcutaneous method in its application in the treatment of the diseases caused by pathogenic organisms. The work is arranged according to a new classification, which is an improvement upon that in the former editions, the best features of which have been largely retained. Altogether it is a work to be highly recommended.

*The Chinese, their Present and Future: Medical, Political, and Social.* By ROBERT COLTMAN, JR., M. D., Surgeon in Charge of the Presbyterian Hospital and Dispensary at Teng Chow Fu, etc. Illustrated with Fifteen Fine Photo-engravings. Philadelphia and London: F. A. Davis, 1891. Pp. viii + 212. [Price, \$1 75.]

WHILE the medical part of this book is not satisfactory to the scientific student of disease, the volume is intensely interesting. The author gives a vivid picture of the peculiar customs and manner of life and thought of the Chinese. His knowledge of the social and political situation receives a striking confirmation in the accounts lately published in the daily papers of the attempts by the ruling classes in China to stir up popular hatred against foreigners.

## BOOKS, ETC., RECEIVED.

A Treatise on Diseases of the Nose and its Accessory Cavities. By Greville Macdonald, M. D. (Lond.), Physician to the Hospital for Diseases of the Throat. Second Edition. London and New York: Macmillan and Co., 1892. Pp. six to 381. [Price, \$2.50.]

Practical Midwifery: A Hand-book of Treatment. By Edward Reynolds, M. D., Fellow of the American Gynæcological Society, etc. With One Hundred and Twenty-one Illustrations. New York: William Wood & Company, 1892. Pp. xiv to 421.

Influenza and the Laws of England concerning Infectious Diseases. A Paper read before the Society of Medical Officers of Health, January 18, 1892, by Richard Sisley, M. D. Lond., M. R. C. P. Lond. To which is appended Counsel's Opinion on the Powers of Sanitary Authorities as to Influenza, and the Proclamation issued at Dover by the Borough Authorities. London: Longmans, Green, & Co., 1892.

Les tumeurs de la vessie. Par J. Albarran, Chef de clinique des maladies des voies urinaires, etc. Préface par le professeur F. Guyon. 75 figures et 9 planches. Paris: G. Steinheil, 1892. Pp. xi to 494.

Nouvelles doctrines de neuropathologie, d'après les leçons élémentaires de clinique médicale professées à l'Hôtel-Dieu de Toulouse. Par le Docteur Caubet, Professeur de clinique médicale, etc. Examen critique par le Docteur L. Chabbert, ancien interne des hôpitaux. Paris: V. Babé et cie., 1892. Pp. 112. [*Publications de l'Echo médical.*]

Reaction of the Amide Group upon the Wasting Animal Economy. By Professor Samuel G. Dixon, M. D., and Professor W. S. Zuill, M. D., D. V. S. [Reprinted from the *Times and Register.*]

Neuroma, with Report of a Case. By Edmund J. A. Rogers, M. D., Denver. [Reprinted from the *Medical News.*]

Laparotomy under Cocaine. By Emory Lanphear, M. D., Kansas City, Mo.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland. Semi-annual Session, held at Cambridge, Md., November, 1890. Ninety-third Annual Session, held at Baltimore, Md., April, 1891.

Seventy-eighth Annual Report of the Trustees of the Massachusetts General Hospital and McLean Asylum, 1891.

A Primer of Materia Medica for Practitioners of Homœopathy. By Dr. Timothy Field Allen. Philadelphia: Boericke and Tafel, 1892. Pp. iv-5 to 498.

The Responsibilities of the Medical Profession. An Address to the Graduating Class at the Commencement of the Albany Medical College, March 16, 1887. By Andrew S. Draper, State Superintendent of Public Instruction.

Psycho-therapeutics; or, Treatment by Hypnotism and Suggestion. By C. Lloyd Tuckey, M. D., Member of the Medico-psychological Association. Third Edition, revised and enlarged. London: Baillière, Tindall, and Cox, 1891. Pp. xvi to 321. [Price, \$2.]

## Miscellany.

A Year's Work in Minor Surgical Gynæcology at the Kensington Hospital for Women, Philadelphia, was reported upon recently by Dr. Charles P. Noble, at a meeting of the Philadelphia County Medical Society. Speaking of operations on the uterus, Dr. Noble said:

I have made it an invariable rule to re-examine all patients before beginning the operation. This can be done most thoroughly when the patient is anesthetized. If the uterine appendages are found inflamed and adherent, any proposed operation upon the uterus is abandoned. I believe this to be the only safe rule of practice. For sutures, silk, catgut, and silkworm gut have been used. For general purposes I like silk; but it should not be used where the sutures can not be removed in one or two weeks. Catgut I have found very useful for sutures having but little strain to bear, as, for instance, the upper sutures in perineal operations. Silkworm-gut has the advantage that it is non-absorbent; hence it is to be preferred where sutures must be left in a long time—as, for instance, in the cervix, when the cervix and perineum are repaired at the same sitting. It has the disadvantage of being stiff, which property makes it somewhat hard to remove, and gives the patient some pain. After operations the vagina is carefully dried, a pencil of iodoform (twenty-five grains), together with a strip of iodoform gauze, is introduced, the vulva is sprinkled with a powder of iodoform

(one part) and boric acid (seven parts), and then a cotton pad is placed over the vulva—held in place by a T-bandage. For perineal operations the urine is drawn for two days, after which the patient is allowed to urinate. The gauze is removed after forty-eight hours, after which a sublimate douche (1 to 2,000) is given daily. The bowels are moved on the second day and regularly thereafter. An abundant soft diet is permitted. The external sutures in perineal operations are removed about the eighth day; the internal sutures at the end of the second week. When the cervix has been repaired at the same time, the cervical sutures are removed at the end of the third week, or even later. One should err on the side of leaving the sutures in long rather than that of removing them early.

Patients having perineal operations are permitted to sit up in two weeks; those having a curetting, in three or four days; those having a trachelorrhaphy, in a week, etc.

The secret of success in plastic surgery is good asepsis, and careful, painstaking, and accurate denudation and suturing. I have never failed to secure good union, which has always been primary throughout, with two exceptions—one stitch-hole abscess and one small hæmorrhage (hæmatoma).

On the procedures of dilatation and curetting of the uterus the author said: Within the past ten years professional opinion concerning these operations has fluctuated widely. Before the antiseptic era curetting was considered a dangerous operation. Its danger at that time I feel satisfied was due partly to lack of antiseptic measures, and partly to bad diagnoses. At that time our knowledge of the diagnosis of chronic salpingitis was very imperfect, and many accidents (peritonitis) resulted from operating on the uterus when the tubes contained pus or other septic fluid. Since the antiseptic era, in the hands of men capable of making a diagnosis of uncomplicated disease of the uterus, and of excluding chronic pelvic inflammation, these operations have been done with impunity. Of late, the legitimacy of the operations has been questioned by Dr. Joseph Price, on the ground that many cases of salpingitis and pus tubes have come under his care in which dilatation or curetting has been done. This fact is no argument against the legitimacy of the operations, nor against the fact that, when properly done in uncomplicated cases, the operations are perfectly safe and free from danger.

Did the women seen by Dr. Price (and by others, including myself) have the tubal disease before the uterus was dilated or curetted? Were the operations done under rigid asepsis? I believe that blunders in diagnosis and blunders in asepsis should bear the blame in these most unfortunate cases, and not legitimate surgery. In my own hands no such untoward results have occurred. On the contrary, under the strict limitations laid down, my confidence in the value and safety of the operations increases as my experience grows.

*Dysmenorrhœa.*—Three cases of dysmenorrhœa, due to partial development of the cervix, with antelexion, and characterized by "cramps" during the flow, were treated by dilatation. Dilatation in this class of cases has always given good results. The cause of the "cramps" is a poorly developed cervix with a narrow canal, whose caliber is further lessened by the antelexion. A broader experience has induced me to use the dilator for dysmenorrhœa much less frequently than formerly. I consider it absolutely contra-indicated if there is tubal inflammation, and believe that it is of little use in relieving pain, unless the latter is distinctly intermittent and cramp-like in character. The pains accompanying menstruation due to inflammation of the uterine appendages, or of the uterus, or due to a depressed state of the blood, with pelvic neuralgias, are not benefited by dilatation, and in such cases it should not be done.

*Endometritis.*—Fifteen cases of uncomplicated endometritis have been treated by dilatation and curetting. Nine of these were cases of fungoid endometritis with resulting uterine hæmorrhages. I believe that this procedure best meets the indications in all cases of uncomplicated chronic endometritis. By removing the thickened portion of the diseased endometrium and providing a freer vent for the uterine secretions, most cases of endometritis can be cured promptly, and the remainder are much improved. The number of cases in which it is necessary to make intra-uterine applications is thus much reduced, and these women are saved the necessity of undergoing a prolonged course of painful intra-uterine treatment. By promptly curing women

with chronic endometritis another important point is gained—the disease is cured before it spreads to the tubes.

The results in my hands have been most satisfactory in cases of fungoid endometritis, especially those of short duration, resulting from abortions. Cases of chronic endometritis with purulent leucorrhœa have been most intractable, and in these cases it has been necessary to make weekly applications to the endometrium (by means of the applicator) of pure carbolic acid, Churchill's tincture of iodine, or a saturated solution of chloride of zinc for some weeks *after* the curetting. I wish to call attention to the small number of cases of uncomplicated endometritis in this series. Omitting the fungoid cases, there were 6 out of 128 women admitted to the hospital. This is about the average in my practice.

In fungoid endometritis I have found the curette so valuable and other methods of treatment (in marked cases) so futile that I am unable to understand how those gentlemen who oppose the use of the curette treat these cases. The only other resort is electricity; but the curette will accomplish in a few minutes what it requires weeks or even months to accomplish by electricity.

The results obtained by the curette in uncomplicated endometritis are so good that of late, forgetting the teachings of past experience, certain operators have proposed to treat cases of endometritis complicated by chronic tubo-ovarian inflammation in the same way. It seems to me that careful men can not protest too strongly against such treatment. In the first place, the danger of setting up fresh salpingitis and peritonitis is acknowledged (except by the few) to be great; and in the second place, should the endometritis be cured (which is doubtful, because of pelvic congestion kept up by the tubo-ovarian inflammation), the graver disease of the appendages remains. The wiser plan, if the appendages are diseased, is first to remove them, and then actively treat the endometritis; or, if the appendages are but slightly diseased and do not require ablation, to treat the patient by applications of iodine to the vaginal vault, and the use of glycerin tampons, at the same time using every measure to improve the local conditions by general medication.

It happens not infrequently that when the inflamed uterine appendages are removed, an endometritis is left which causes the patient some annoyance. These cases are often reported by those hostile to modern surgery, as showing that the abdominal section has failed to cure the patient. These gentlemen have a mental strabismus, and do not see that the section has accomplished the end aimed at—the ablation of the diseased uterine appendages. Whether this alone will cure the patient depends upon whether the particular patient has any other disease. If she has an endometritis, this must be cured; if anæmia, or indigestion, or malnutrition, these must be treated.

I wish to protest against the view that endometritis, as a rule, causes much distress, except the annoyance of a leucorrhœa, unless it induces hæmorrhage. Where women having endometritis suffer much pelvic pain and are semi-invalids, the cause of the pain or invalidism is to be sought elsewhere—in the uterine appendages or in the vital organs or blood state. It is a narrow man who attributes all the symptoms complained of by women to disease of the pelvic organs, and who forgets that women have an unstable nervous system, easily influenced by morbid conditions of the general economy.

In discussing endometritis it should not be forgotten that other conditions besides endometritis can cause a discharge from the uterus. Whatever will cause congestion of the uterus will cause uterine discharge. For example, subinvolution, constipation, feeble heart, lazy habits, malnutrition as from phthisis, erotism, etc. Treatment addressed to the causative disorder will stop such uterine discharge. This class of cases calls for no treatment of the endometrium.

**A Pernicious Osseous Disease (Lymphadenia Ossium).**—The *Journal of the American Medical Association* for March 12th contains the following editorial article:

A pernicious form of osseous disease is the subject of a Vienna clinical prelection by Professor Nothnagel, given in full in two recent numbers of the *Press and Circular*. The changes of structure discovered by autopsy were unusual in extent, having invaded the entire skeleton and obliterated the medulla of the bones by a perversion of that force or those forces whose "elaboration should constantly proceed in the

healthy hæmatic organs." The case was that of a male, aged twenty-four years, hitherto healthy, with good family history, and living in fairly hygienic surroundings. He was first a "Schwizer," or cowherd, and later a soldier in a small Tyrol barracks. His attack dates from eighteen months ago, with fever and pain in the breast and limbs, without appreciable cause. The temperature was not recorded accurately until a month before death. Sweating was profuse at the onset of the attack, and also in the later months. Intermissions in the paroxysms of pain and fever were about two weeks in duration, with excellent health, as regarded subjective symptoms, in the intervals; later, however, the attacks became more frequent and more intense, occurring in the evening and with a periodicity resembling that of tertian malarial fever. The patient became pale and emaciated. The sternum and long bones of the extremities showed deformity from thickening. There was a right-sided exudative pleurisy which increased gradually until death. The spleen was slightly increased in area. The urine exhibited no albumin or sugar, but indican was in excess. The blood revealed oligocythæmia and oligochromæmia, and under Ehrlich's coloring commingling apparatus there was reported poikilocytosis, the erythrocytes showed a marked disparity of diameters—ranging from microcytes to the normal red cell—and a few of the red corpuscles were observed to contain single nuclei; the leucocytes were not greatly changed. The blood was examined at different times for the parasites of malarial fever, but none were observed. Bacterial examinations obtained only negative response.

The autopsy was made by Professor Kundrat on November 17th, or six weeks after the patient's entrance into the hospital. The condition of the bones was the most striking feature of the case. Every bone of the spine, pelvis, shoulders, the sternum, ribs, clavicles, all the long bones, the carpals and tarsals, were affected. The unchanged bones were the phalanges and those of the head and face. A thick layer of osseous deposit, as if covered with a thick infiltrated periosteum, caused the exterior deformity. All the long tubular bones were expanded at their upper portion by a grayish-white infiltrated earthy matter. The interior of the long bones, and of the larger spongy bones, was occupied by the same metamorphic deposit as appeared on their exterior. In a few places the muscular insertions were infiltrated with the same substance. The marrow of the bones, with the exception of a remnant here and there, had disappeared. No bending or twisting of the bones was present as is described to occur in *osteitis deformans*. The lymphatic glands were found enlarged, in some cases twice and even thrice their normal size. During life they could be felt to be soft and large, and the post-mortem confirmed this condition, they being in no way indurated. When cut, the glandular tissue appeared congested, due to a hyperplasia of the follicular elements, but otherwise it had a normal appearance.

The pathology of the disease seems to hinge upon a deranged hæmatic process, affecting chiefly the regeneration of the red corpuscles. The leucocytes remained almost unchanged, indicating that they were derived from lymphatics and spleen and not from the marrow of the bones. The red corpuscles were greatly reduced in number and presented a wide range in regard to their diameters, thus conveying the thought that they were the imperfect product of the spleen, unaided by the better results afforded normally by the marrow of the bones. All investigators are not agreed as to the part which the bone marrow plays in the formation of the red corpuscles, but this case would appear to bring that function as far to the front as has been taught by any of them. The argument by analogy disposes us to believe that the pathology in any case which would arise from a functional or anatomical disorder of any one of several organs, physiologically working together for the same end, would overtax the others and create in them a compensating hypertrophy. Thus, when the spleen is extirpated, a compensatory activity is found by Mosler to be thrown on the medulla ossium and lymphatic glands. In this case the medullary structure was almost obliterated, and practically evaded the splenic experiment, throwing back a compensation of function on the spleen and lymphatic glands and augmenting the volume of those organs. These changes were recognized during life and abundantly confirmed at the post-mortem table. This remarkable case is differentiated by Nothnagel from acromegaly, and one or two other forms of osseous disease, and designated "Lymphadenia

(or lymphadenoma) ossium," due to a gradual obliteration of the medulla, "in a manner not yet demonstrated by experiment, but probably induced by a compensating force for the altered state of elaboration that should constantly proceed in the healthy hæmatic organs."

**The Ambulance Service in New York.**—The newspapers have published the following letter, dated March 26th, signed by Dr. Charles McBurney and Dr. Lewis A. Stimson:

Within the last few weeks the newspapers have printed a number of articles criticising with considerable severity the ambulance service of this city. This criticism has usually accompanied and been based upon reports of alleged negligence or ignorance on the part of ambulance surgeons, or of such lack of sympathy in the performance of their duties as would amount, if true, to actual brutality. The other side of the case has been partly presented in an occasional article and in editorial comments, but the great majority of the publications have been occupied solely with the alleged errors and defects of the service. In view of this fact, it has seemed desirable to friends of organized charity that some of those who are familiar with the subject should make to the public a statement of the character of the ambulance service, and of the conditions under which it is performed, to the end that an opportunity may be given to those who are interested in the matter to form a trustworthy opinion as to its merits and demerits.

The undersigned are now, and for some years have been, attending surgeons at the Roosevelt and New York Hospitals, respectively; they take part in the selection of the ambulance surgeons, supervise their work, and have charge of the patients brought in by the ambulances. They have also served in the same capacity at Bellevue and other hospitals.

The ambulance service of the city is carried on partly by the Commissioners of Charities and Correction at Bellevue, Gouverneur, and Harlem Hospitals, and in part by a few of the private hospitals—the New York, with its Chambers Street branch; the Roosevelt, the St. Vincent, the Presbyterian, and the Manhattan.

The statements that we have to make are based in detail upon the conditions existing at the New York, Chambers Street, and Roosevelt; but, to the best of our knowledge and belief, they are equally true in general of the other hospitals, both public and private.

Each of these three hospitals provides two ambulances with relays of horses, drivers, and stablemen. The stable and harness arrangements are similar to those in use by the Fire Department, so that within a minute after the signal has been given from the office of the hospital the ambulance has departed on its errand. This is the invariable practice, and the rule of the hospital is and long has been rigid that an ambulance surgeon while on duty shall not go out of hearing of the gong that summons him to a call. At night the signal sounds simultaneously in his bedroom and, at the New York, turns on the electric light. One ambulance surgeon is always on duty, and is required instantly to leave whatever other work he may be engaged in when the call sounds. A second surgeon is required to hold himself in readiness to answer any call that may come during the absence of the first. It occasionally happens that a third call comes while both ambulances are out, or a second call while one ambulance is temporarily disabled, and those are the only occasions on which any delay in answering a call arises within the hospital. The Grand Jury stated officially last July that the ambulance habitually reached the farthest points in the largest district within eight minutes after the receipt of the call, and that delay occurred only in the transmission of the call to the hospital.

The call for an ambulance is transmitted to the hospital by one of two routes; it may be sent from a station-house to Police Headquarters and thence by private telephone to the hospital, or it may come over the Fire Department wires, for the fire-alarm boxes are so fitted that a policeman can send a call for an ambulance from most of them. These latter calls sound simultaneously in all the hospitals, and the case belongs to the ambulance that gets to it first. In connection with this it may be mentioned that a great deal of harsh newspaper criticism has been based on the theory that an ambulance surgeon refuses to take a patient who is not in his district. On the contrary, he is anxious to take him, for almost the only break in the monotony of a duty that deals solely with sickness and suffering is the satisfaction that comes

from a "beat" of the ambulance of a neighboring hospital. These fire-alarm calls are known as "hurry calls," and they are the ones that especially bring the young man down stairs three steps at a time to swing himself bareheaded to the tailboard and urge the horse to a run.

A book is kept in the office in which the time of the departure and return of the ambulance, the place where the patient was found, and the diagnosis are recorded.

The ambulance surgeon is a member of the resident staff, who is assigned to this duty during the middle period of his hospital course—that is, after he has already passed one term in preparation for it. The members of the staff are selected, after a competitive examination, from among candidates who are many times more numerous than there are positions to be filled, and they are beyond question the very best of those who are graduated from Harvard, Yale, and Philadelphia, to try for the positions. All of them have had previous experience as dressers in dispensaries and as substitutes in hospitals. At Chambers Street the men are not selected by competitive examination; the peculiar character and activity of that service make it exceptionally advantageous to men of experience, and consequently the members of its staff are usually (three fourths of the time) men who have previously served a full course in some other hospital.

What is the work for the doing of which this elaborate preparation is made? It is to respond to any call that is sent in by the police; to respond instantly, unhesitatingly, at any hour day or night, abandoning everything else, and without stopping to inquire as to the character or the urgency of the call. Primarily, it was intended only for the care and comfort of those who need to be received into a hospital, but it has grown into a vast additional system of outdoor relief, of the treatment of the immediate wants of those who do not need hospital care. This needs to be borne in mind in criticising alleged refusals to receive patients. In a large proportion of calls neither the sender of the call nor the patient has any expectation that hospital care will be required or accepted.

The amount of the work is indicated by the following figures: During the year 1891 the Chambers Street ambulance was called out 3,946 times; the New York, 1,200; the Roosevelt, 1,500. The Grand Jury found the daily average for the city 47 calls.

It can hardly be necessary to say that a private hospital is a private charity and is under no obligation to maintain this service (indeed, many hospitals do not maintain it), or that it receives no pay for doing it, or that no member of its professional staff receives any pay for it. And yet, so easily does the notion of a vested right arise from a recurrent favor, that one of our hospitals was severely criticised by the press because it objected to going to the expense (some \$2,000) of making a new connection with the Fire Department wires after the latter had been placed in the subway.

Much of this work is work that the city pays other people to do. Police surgeons are employed and paid to attend to sick and injured policemen and to such sick or injured citizens as are brought to the station houses. But it is very much easier, as well as more certain in its results, to press a button and summon an ambulance than it is to send a messenger a mile or two for a physician who may or may not be at home.

Further, a considerable number of the calls are made needlessly for trifling injuries, for bruises received in a drunken altercation, for malingering tramps who want a night's rest and a breakfast and had rather ride than walk. The habit of calling increases with use, and without stopping to consider the urgency, the signal is rung, and horse, driver, and surgeon are brought out to put on a piece of court plaster. The hospitals make no complaint of this abuse; they look upon it as an inevitable accident of the service. It means to the management a little more money spent for repairs, or for horses, or perhaps for wages. It means nothing to the attending staff, for it brings them no cases to be treated, but to the ambulance surgeon, who has not even the privilege of an audible grumble, it means a great deal; it means the needless interruption of other work, the loss of food or sleep, and the strain on nerves and temper which that interruption and that needlessness create. Even without such avoidable additions the work is heavy enough and trying enough to call for all the sympathy and all the charity in judgment that their critics can command. A few days ago the Press Club made an appropriate and touching recognition of the fidelity of a re-

porter who recently died of typhus fever contracted in the discharge of his duty. For the last two months the ambulance surgeons of this city have been going daily, and several times a day, to cases which they knew might be, and many of which proved to be, typhus; and within a week one of them, called to such a case, saw every friend of the patient rush from the room when the dreaded word was spoken, and he was compelled to take him in his arms and carry him to the ambulance alone and unaided. With the experience and prospect of such exposures and of personal violence frequently threatened and occasionally inflicted, the life of the ambulance surgeon does not excite much envy; and when to it is added the constant exhaustion of exacting duties we can only feel surprise that men are willing to take the places. They frequently fall ill from overwork or through contagion, and occasionally one dies. Look at the great tablet in Bellevue Hospital covered with the names of young men who have "died in the discharge of duty." These young men are the best of their age in the profession; they have eagerly competed for the opportunity to assume their onerous duties, and they perform them with a fidelity and zeal that are rarely exhibited in other places, for their work is done under the stimulus of a desire for self-improvement, not for money.

This side of the story is not generally known. The public hears nothing of the good work faithfully done beyond the half dozen items in each day's newspaper that "an ambulance was called and the injured man taken to the hospital." Attention is aroused only by the occasional error or by the picturesque and imaginative accounts for which our long indulgence in sensationalism has created a demand.

It is sometimes urged by critics who are apparently without a personal knowledge of the workings of the service that it should be in the hands of older men in order that mistakes, presumably due to ignorance and inexperience, should be avoided. But older men of more experience and knowledge, and of equal ability, are not to be had. An older man who would accept such a position for such a salary as a hospital could pay would be a self-confessed failure, and any expectation of better work from him would certainly be disappointed. Such extraordinary exertions as are made by the young ambulance surgeons in the performance of their duties can be made continuously only by the young, the vigorous, the enthusiastic. If they were not earnest and eager in their work they would not remain in the service a week. The elderly man of experience, for whom the coroner's jury yearns, who should attempt to take the place of one of these young men, would at the end of a few days be in as pitiable a condition as if he had acted as a substitute on one of our college football teams.

Of course, we admit that occasionally an important mistake is made. That mistake is almost always the same—a fracture of the skull without symptoms is overlooked in a drunken man, or the symptoms produced by it in a sober man are thought to be those of drunkenness. It is not necessary to plead in extenuation that for each of these mistakes there are hundreds of cases in which the same judgment is exercised and a correct decision reached, or that little or no actual harm arises from it. The defense has a much broader and more solid foundation. Those mistakes have always been made and are now being made everywhere, and by the most experienced, and they will doubtless continue to be made so long as our perceptions and our knowledge have their present limitations. The science and art of medicine has not yet made it possible to recognize a fracture of the skull that gives no symptoms, or surely to discriminate between some of its symptoms and those of alcoholic intoxication. To the retort that, such being the case, every doubtful case should be taken to the hospital, we reply that that very course is the one that is habitually followed. The occasional mistake is made in cases which, after due consideration, have been thought not to be doubtful. The doubtful cases which are taken in are never heard of outside the hospital, and yet they are to be counted by the hundreds. Upward of ten per cent. of the patients brought in by ambulance are just those doubtful cases; they are brought in on the chance; they prove to be nothing but drunkenness, and they are discharged the next day. The hospitals do not pretend to take care of the drunken; they do not refuse a sick man because he is drunk or violent or abusive, but they do not take him if they think he is only drunk.

Finally, we beg leave to add a few extracts from an official state-

ment made by the Grand Jury last July. A committee of five members was appointed "to make a thorough examination of the ambulance system of the city of New York." That committee reported as follows:

"Regarding the private hospitals, . . . we can only say that we found in their ambulance equipment, and in their administration of the service, only that which calls for our hearty approval."

"We note with commendation a feature that seems universal in the hospitals named (the private ones), to wit, that the ambulance doctors are all graduates, and that they are not detailed for ambulance service until after they have performed six months of active duty in the hospital wards."

"In all these hospitals, both private and public, we found admirable equipments for the performance of the important labor discharged by them, and a commendable zeal to be very prompt in responding to the demands for the service."

"While we find very much to commend regarding the response by all hospitals to ambulance calls on them, we are compelled to criticize very severely the present lack of adequate official means of conveying prompt notification to the hospitals of the necessity for an ambulance . . ."

The following communication on the same subject, entitled *Youthful Ambulance Surgeons*, and signed "An Old 'Doctor and Surgeon,'" appeared a few days ago in the *Evening Post*:

The innate and inalienable sapience of the average jurymen, and the eminently sagacious results of crown's-quest laws, have seldom been more admirably illustrated than in the verdict recently delivered upon the "Harper case," condemning the youth of the ambulance surgeons and house staff of our hospitals, and urging that "the authorities" (what particular "authorities," imagination is left to surmise) should insist that "experienced doctors and surgeons" be assigned to such positions.

From a strictly nosocomial point of view, it must be admitted that an ideal perfection of medical relief would be attained if, for example, Dr. Lewis A. Sayre and Dr. Stephen Smith were kept at a hospital, day and night, to attend to ambulance calls, and if the resident staff were entirely composed of men like Dr. Weir, Dr. Gouley, Dr. Bull, Dr. McBurney, Dr. Bryant, Dr. Dennis, Dr. Jaueway, Dr. Loomis, and others of equal professional eminence. But, unfortunately, even under our present somewhat arbitrary method of legislation, no way exists of forcing these gentlemen to relinquish a lucrative practice, to abandon their families and homes, and to devote their whole time to gratuitous work.

The system of hospital administration seems to be strangely misunderstood by the public, and sometimes by the press. The ablest and most "experienced doctors and surgeons" have, for generation after generation, been "placed in charge" of our hospital wards, and have given their service without remuneration as members of the visiting or consulting staff. In their daily rounds of the hospital, it is not too much to say that the poorest patient receives more skilled treatment than the ordinary coroner's jurymen could afford to pay for, and it is certain that the most brilliant triumphs of surgery and medicine have been achieved in hospital practice.

As regards the younger men who constitute the resident staff—always under instruction of the "visiting," except in manifestly minor cases—it is probably not generally known that these are all graduated physicians and surgeons who, after a course of instruction which now includes more clinical experience than the graduate of the last generation could acquire in ten years of private practice, undergoes, after receiving his diploma, a competitive examination to win his hospital appointment, in which he rises, progressively, from the lowest to the highest grade. In fact, these younger men form a *corps d'élite* by selection from our best medical schools.

It is possible that drunkenness may mask an injury to the skull or its contents, or, more rarely, that such an injury may simulate drunkenness; but, in such cases, time for the development of further symptoms is usually needed to form an accurate diagnosis, even by the most expert seniors.

On the other hand, the *Times and Register*, a medical journal edited in Philadelphia, in an editorial article headed *Great Charities and Puerile Administration*, has this to say of the hospital internes of New York:

New York is having trouble with her ambulance system. The youngest and most inexperienced resident, still top-heavy with the dignity of his newly acquired doctorate degree, is the one usually sent to answer calls for the ambulance. The result is seen in two cases recently described in the journals. An aged woman was run over and seriously injured. The Roosevelt Hospital ambulance was summoned, but the doctor in charge refused to receive the woman and drove off, although urged by two physicians present to take the woman to the hospital. So indignant were the bystanders that they pelted the doctor and ambulance with snowballs as they drove off.

What a comment is this on the description of this hospital by a British visitor, quoted in a recent New York medical publication! He speaks of the magnificent operating theatre, the finest in the world, and of the difficulties experienced in finding ways of expending the enormous sum (\$400,000) given to the hospital for that purpose.

In another case the coroner's jury censured the ambulance surgeon of Manhattan Hospital for shameful neglect of a man with a fractured skull, their verdict ending as follows:

"We condemn the treatment of the ambulance surgeon who had charge of the case, as well as the surgeons of Bellevue Hospital, under whose charge the deceased was placed. We further condemn the practice of the hospitals of having young and inexperienced doctors, and we strongly recommend that the hospitals be censured, and that if the authorities have the jurisdiction they should insist that experienced doctors and surgeons be placed in charge, so as to protect the lives of the unfortunates who may be placed in their charge."

It is thus seen that the grandest designs of philanthropists may be brought to naught by the selection of improper instruments. It is one of the grave defects of the examination system that it can not determine the fitness of candidates beyond their proficiency in study. "Though I have the gift of prophecy, and understand all mysteries and all knowledge, and though I have all faith, so that I could remove mountains, and have not charity, I am nothing."

[Our own view of this subject was given in the *Journal* for February 6th.]

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. Walter Wyman, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for April 1st:

CITIES.	Week ending—	Population, U. S. Census of 1890.	Total deaths from all causes.	DEATHS FROM—									
				Phthisis pulmonalis.	Yellow fever.	Small-pox.	Varicella.	Scarlet fever.	Enteric fever.	Diphtheria.	Measles.	Whooping-cough.	
New York, N. Y.	Mar. 26.	1,515,301	872	105					4	31	30	15	5
Chicago, Ill.	Mar. 19.	1,099,850	448	32					18	6	20	2	2
Philadelphia, Pa.	Mar. 19.	1,046,964	504	55					12	18	28	2	2
Brooklyn, N. Y.	Mar. 26.	806,342	397	48					12	15	3	3	3
Boston, Mass.	Mar. 26.	448,477	237	24					2	3	10	1	1
Baltimore, Md.	Mar. 26.	454,439	220	30					1	16	16	4	1
Cincinnati, Ohio.	Mar. 25.	296,908	137	11					1	3	8		
Cleveland, Ohio.	Mar. 26.	261,353	109	10					3	1	2		1

**Moliere and Physicians.**—The *New York Times* publishes a notice of a book by M. Georges Monval, entitled *L'Amour médecin*, from which we take the following: Several Moliéristes, and Monval is one of them, think that Molière hated physicians because he was ill and the physicians could not cure him, but Molière knew well that his malady came

of his stage life; the monster public had to be incessantly tamed, and there was abuse of exasperated strength, excess of mental labor. The remedy was to be found in an abandonment of the theatre. He was too sensible to blame the physicians for his ill-health; still he hated them, as *L'Amour médecin* proves, and perhaps his sentiment may be explained by pure professional jealousy. In love with truth and frankness, Molière felt deeply the pain of playing a part that he unjustly condemned in his enemies—the part of a physician who does not cure.

Comedy does not transform men and manners; it can not more realize this anti-natural miracle than medicine can change a temperament. It has higher and grander achievements. It shows in the work of Molière instinct, youth, love, unconquerable forces triumphant over the human vices at war against them, and all-powerful Nature, protected by an invincible armor of adamant, a tamer of the false and fictitious in misdirected civilization. Like medicine, comedy has for its function to prevent Nature from deviating. It does not cure the incurable. In attacking the physicians Molière confessed figuratively his own inability to repair the irreparable. He never missed an opportunity to express contempt for books; he feigned to believe that the dramatic poet can not live and remain in the memory of men except by representation on the stage.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Original Communications.

THE ELEMENT OF  
CONTAGION IN TUBERCULOSIS.\*

BY T. MITCHELL PRUDDEN, M. D.

THE two great achievements in medicine which especially mark the decade now closing are the gaining of precision in our knowledge of the cause of infectious diseases, and directly based upon this the discovery that, in a degree scarcely dreamed of before, these diseases are preventable.

The medical world was all ready for Dr. Koch's announcement, when it came early in 1882, that tuberculosis was caused by a living germ whose life history he then made known. It is a small rod-like germ, very persistent in the maintenance of its form and life, but so sensitive in its growth and reproduction that it has no breeding places in Nature outside of the bodies of those men and animals in which it has lighted up disease. Finding lodgment in this congenial soil, it may grow, stimulating and poisoning, as it does so, the tissues where it lies, so that, sooner or later, the tendency is for the new tissue which is formed and the old which is robbed of life to disintegrate, and if favorably situated be by degrees cast off from the body together with more or less of the virulent germs.

While the tubercle bacillus does not grow in Nature outside the bodies of warm-blooded animals, and while its life is destroyed by a few moments of boiling, by contact with many chemical agents, and by prolonged exposure to the sunlight, it yet may retain its vitality and virulence during months of drying and the ordinary exposure to the weather, and may be found alive after long burial in the earth.

The places outside of the bodies of living beings in which the bacillus of tuberculosis is to be especially found under ordinary conditions with us are in the flesh and milk and discharges of tubercular cattle and in the excretions of tubercular persons, especially of those who are the victims of tuberculosis of the lungs. But by far and away the most common and abundant lurking place of this germ is the sputum in pulmonary tuberculosis.

When the tubercle bacilli are cast off from the body in the sputum, they are closely imbedded in a moist, tenacious, albuminous material from which they can not escape so long as moisture is maintained, no matter where they lodge or what air currents may blow over them. So that, so far as specific contamination of the air is concerned, this can not occur while the sputum stays moist. This same tenacious envelope also prevents such ready access of disinfectants to the bacilli in the sputum as would assure their easy destruction. When the sputum dries, the bacilli are still firmly held in place so long as the desiccated mass remains intact. But let this once be pulverized by the foot on floor or carpet, by rubbing between folds of cloth or in any other way, and these virulent particles can mingle at once with other

dust and become subject to the same physical laws of transport and diffusion.

It is to be distinctly understood that the breath of consumptives, apart from solid particles which may now and then be cast off in coughing, conveys no germs.

It is not necessary for me to go over the story of research and experiment which have led to the universal conviction that the tubercle bacillus stands in an absolute and direct causal relationship to tuberculosis, and that in this relationship it stands alone.

That there are many contributory factors in the acquirement of this disease—vulnerabilities of the individual, both hereditary and acquired, predisposing vicissitudes of environment—one can not, it seems to me, deny, nor should he measure lightly. But the one thing without which tuberculosis can not come to man or beast is the living tubercle bacillus. All the vulnerabilities and predispositions and favoring vicissitudes which we either know or can conceive of can not without this particular germ light up this particular disease. It is not a vapor in the air, it is not a mysterious miasm, it is not an inscrutable enzyme which does this thing, but a definite physical body which we can see and measure with our lenses, which we can cultivate and handle and kill.

Precision in our conception of the nature of the disease tuberculosis, definiteness in our knowledge of its cause—these were the first fruits to ripen in this newly opened field.

But then came the question, If tubercle bacilli are cast off alive from the bodies of its victims or can be consumed in the meat and milk of tubercular cattle, are not these cast-off or consumed germs the sources from which new disease is propagated? If this were true, then tuberculosis is a communicable disease. I will not weary you, full as it is of practical significance, with the oft-told tale of Cornet's convincing researches, nor with a summary of other studies which at last have proved beyond a doubt that living virulent tubercle bacilli are present in the dust of the air of places in which uncleanly consumptives live, and that close attendance upon and association with such persons, without intelligent precaution, frequently involves acquirement of the disease. The evidence of the communicability of tuberculosis finds a most dramatic index in the yearly death roll of its victims.

Slowly but surely we have learned that what once was thought to be hereditary transmission of the disease is often only household poisoning, or, at most, an entailed vulnerability in the presence of the germs derived from whatever external source. The possibility of extremely infrequent direct hereditary transmission of the tubercle bacillus need have no serious consideration here, in view of the immediate practical purpose which calls us together. The main point is that tuberculosis is a communicable disease, and that the chief element in its conveyance is the unhealed-for sputum of the victims of pulmonary tuberculosis. This possibility was distinctly foreshadowed in Dr. Koch's first communication on this subject, and has since been steadily growing into a fixed conviction among intelligent physicians.

\* Read before the Section in Hygiene of the New York Academy of Medicine, January 21, 1892, as the introduction to a discussion on the prevention of tuberculosis.

And yet well-nigh ten years have gone without that persistent and concerted action on the part of medical men in this country which both intelligence and humanity would seem to make imperative. The varied reasons for this apathy we need not here discuss.

But now, at last, when all seems ready for decisive measures, we must not forget that our own ideas of the danger to be met must be precise and definite, in order that we may by individual counsel, as well as by public urgency, make plain and comprehensible to all the thing we strive to do. There should be among ourselves none of the old indefiniteness of conception regarding the exact meaning of such terms as infection, infectious disease, contagium, contagiousness, and the like.

The meaning of these terms was of necessity uncertain and hazy when the things themselves which they were intended to specify were largely matters of speculation and conjecture. It were well, perhaps, if they were dropped wholly from our speech and replaced by new words coined in the new light. But as this may not be, the next best thing is to remodel the meaning, and with this to reinvest the words.

I think I do not err in saying that those who can justly speak most authoritatively in this matter are agreed that in the light of to-day an *infectious disease* is one which is caused by the invasion and reproduction within the body of pathogenic micro-organisms; not necessarily an invasion by bacteria, because in one case at least—malaria—the invading pathogenic micro-organism is not a bacterium, but belongs to a wholly different class. The invading micro-organisms which we must assume to cause the exanthemata are wholly unknown to us, but the nature of these diseases justifies us in grouping them with those infectious diseases whose causative agent is definitely known. *Infection* is the condition produced by the entrance and multiplication of pathogenic micro-organisms within the body.

The word contagious no longer covers infinite possibilities in the unknown, or carries with it the mysterious terrors of the unknowable. The *contagium* in any infectious disease is for us to-day the particular pathogenic micro-organism itself, whose advent in the body ushers in those reactions of the body cells which we call disease. The contagium of an infectious disease is a particulate thing, which has length and breadth and thickness and weight and the varied powers of lowly forms of life.

An infectious disease is contagious when its contagium—that is, the micro-organism which causes it—under the ordinary conditions of life, can be freed from the body of a diseased person and, by whatever means, conveyed to the body of another in a condition capable of lighting up the disease anew. The old indefinite distinction between infection and contagion, by which one strove to express, among other things, a fundamental difference between the conveyance of disease by personal contact and by aerial transmission, has become impracticable and valueless now, because we know to-day that the differences in the mode of communicability of infectious disease are largely dependent upon the physical qualities of the contagia, upon the places and ways in which these are freed from the body, and upon the

places and ways in which they enter the bodies of new victims.

The moment we know exactly what we mean when we speak of a contagium, the moment we have learned to follow the movements of these particulate contagia as they leave the bodies of their victims—in one case in the stools, in another from the skin, in others from the mucous membranes—and can trace their diffusion and life stories in earth or air or water: the moment, I say, we can bring the light from these varied factors to bear on the clinical stories of infectious disease, we are not only in a condition to talk intelligently about degrees of contagiousness, but to study the conditions under which degrees of contagiousness may vary in nature or be varied by art.

It is an unfortunate circumstance that the most common notion of a contagious disease is derived from those which are most dreaded and most liable to spread—from such diseases as small-pox and scarlet fever—so that the common conception of a contagious disease is of one which necessarily taints the air about the victim—surrounding him, so to say, with an infectious atmosphere. But this notion is wholly groundless in any disease common with us outside of the exanthemata, and is apparently reasonable here only because the contagia of these diseases are unknown to us and are probably largely cast off through the skin, and so easily diffused.

The fact is that such infectious diseases as typhoid fever, diphtheria, and tuberculosis can be highly contagious or made scarcely at all so, depending upon the care or lack of care which is taken by the victims or their attendants in the disposal of their varying exudates or discharges.

How contagious tuberculosis actually is under the conditions which prevail to-day, it is not within the scope of my theme to consider now. But I do not see why it should not continue just as ominous, or become even more so, if the present unsanitary habits continue in public and private places. If the vile and increasing practice of well-nigh indiscriminate spitting goes on unchecked in nearly all assembling places and public conveyances; if the misguided women who trail their skirts through the unspeakable and infectious filth of the street are to be admitted uncleaned into houses and churches and theatres; if theatres and court-rooms and school-houses and cars are to remain the filthy lurking-places of contagia which their ill ventilation and their mostly ignorant and careless so-called cleaning necessarily entail; if in sleeping-cars and hotel bedrooms the well are to follow consumptives in their occupancy without warning or even the poor show of official disinfection; if in ill ventilated and ill-cared-for dwellings the well must breathe again and again the dust-borne seeds of tuberculosis; if no persistent warning is to be given to the ignorant of the dangers which lurk in uncleanness—then our task will be most complex as well as difficult in limiting the contagiousness of tuberculosis.

The task of reform is not less than colossal at best, nor is it by anything less than long-continued and well-directed labor that substantial good can come. It will not do for physicians to say that people will not follow their directions when the danger to the well is not individually more

imminent than this of the acquirement of tuberculosis, and so stand idle. Nor will it answer to hold our hands because, under the most favorable conditions, all will not be reached. Every little helps much when, as here, each victim of tuberculosis may be discharging thousands, if not millions, of virulent germs every day upon our ill-kept streets and in places where the well must go.

It is not logical and it is not humane to do nothing because we may not accomplish all.

How the sputum in tuberculosis can be best rendered harmless it does not fall within the scope of my theme to discuss, nor is the question of tubercular meat and milk upon my list.

But this seems certain: that whatever public and private measures for the prevention of tuberculosis we may decide upon as wise must be so conceived that education will go hand in hand with the law. Tuberculosis is contagious; wise teaching can show that its degree of contagiousness depends largely upon the comportment of the victims themselves.

For humanity's sake the stricken must be made to know that the necessary measures of reform in this matter do not involve ostracism, do not entail isolation.

To make our way between the rigors of necessary legislation on the one hand and the demands of the humanities on the other is a task requiring tact as well as wisdom and large knowledge withal of the daily ways of the world as it goes on outside of laboratories. But, wisely choosing thus the way with caution, let us not forget that death meanwhile holds carnival.

## VICIOUS UNION FOLLOWING POTT'S FRACTURE.

OPERATIVE TREATMENT. PRESENTATION OF A CASE.\*

BY IRVING S. HAYNES, M. D.,

DEMONSTRATOR OF ANATOMY IN THE UNIVERSITY MEDICAL COLLEGE.

A POTT'S fracture is a fracture at the ankle produced by eversion and abduction of the foot.

In a typical case there are three points of fracture, occurring in the following order:

1. A fracture of the internal malleolus.
2. A fracture of the outer margin of the lower articular surface of the tibia adjacent to the fibula.
3. A fracture of the fibula from two to three inches from its lower end.

Often, however, instead of the internal malleolus being fractured, the internal lateral ligament is torn away from its attachment to the malleolus or os calcis, and, instead of fracture of the lower articular margin of the tibia, the interosseous ligament is severed from the tibia or fibula.

The immediate consequences to the limb after such an injury are eversion and outward displacement of the foot and widening of the ankle, due to the separation of the bones forming the mortise of the ankle joint.

There are also disability and three characteristic points

of pain: First, over the seat of fracture of the internal malleolus or rupture of the internal lateral ligament. Second, over the seat of fracture of the fibula. Third, over the front of the ankle corresponding to the injury of the interosseous ligament or adjoining portion of the tibia.

*Occurrence.*—Pott's fracture occurs frequently. As the statistics in the various surgeries are accessible to you all, I will only speak of unrecorded cases. In one hundred and forty-two cases of fracture seen while an interne in Bellevue Hospital, and of which I took full histories, there were twenty-five cases of Pott's fracture pure and simple, or 17.6 + per cent. The other cases were distributed as follows: Head and thorax, sixteen; upper extremity (and clavicle), sixteen; lower extremity (excepting Pott's), eighty-five. These figures are defective in that they do not include the cases for the same time treated as outdoor patients.

*Treatment.*—This consists of immediate reduction of the deformity by *inverting, adducting, and flexing* the foot, using an anæsthetic if necessary, and fixing the foot with plaster-of-Paris bandages over a liberal layer of cotton in a position of *superinversion* and *flexion*—hyperinversion so as to be sure that the internal malleolus will unite in proper position, or, the internal lateral ligament being ruptured, so that it will unite with the least possible lengthening, and that the fibula shall be brought snugly up against the tibia and the mortise of the foot restored. By flexion we seek to prevent posterior displacement of the foot, also recovery with the foot in an extended position, which is a source of discomfort to the patient when he begins to walk.

If there is considerable inflammation, the cotton should be kept soaked with lead-and-opium solution and the limb elevated. The splint should be cut open if there is any constriction as shown by the condition of the toes, which should always be left uncovered for inspection.

When the inflammation subsides, a new plaster splint should be applied over an ordinary Canton-flannel bandage, maintaining the hyperinversion and flexion of the foot. It is not enough to have the toes inverted; be sure the heel is also. Union is usually firm in four weeks. The patient can begin to walk without the plaster splint about the sixth week.

*Sequela after Proper Treatment.*—A stiff ankle which lasts from two to four weeks. If the foot has been kept well flexed during treatment, this will not cause the patient much discomfort. Swelling of the leg, due to the obliteration of some superficial veins, will disappear when the circulation is fully established—usually in from six to eight weeks.

After improper treatment, or failure of treatment, various degrees of deformity result, due to a greater or less outward displacement of the foot, with eversion, a condition similar to that at the outset before the fracture has been treated.

Without speaking further of the varieties of viciously united Pott's fracture, I desire to present the following case as a typical illustration of such an unfavorable result that may occur to any one from a failure to maintain hyperinversion and flexion from the very beginning of the treatment:

\* Read before the Society of the Alumni of Bellevue Hospital, October 7, 1891.

The patient, Daniel McC., an Englishman, aged thirty-eight, a truckman by occupation, entered Bellevue Hospital May 27, 1888, and gave the following history:

*February 8, 1888.*—He jumped from his truck, striking on some ice; he slipped and his left foot turned outward. He was treated at home by placing the ankle between two side-splints taken from a cigar box, and his toes carefully kept in line.

In six or seven weeks he was out of bed, and then it was noticed that his foot was turned outward. He tried to use his foot, and could walk around some with the aid of a cane, but his ankle soon tired and then became painful and caused him so much discomfort that he entered the hospital to secure relief by operative means.

*Examination on Entrance.*—The patient walked with the aid of a cane with difficulty, and could not stand for any length of time on account of the pain on the inside of the ankle. The foot was everted and displaced outward, as shown in Photograph I. (The photograph does not represent the eversion very well, as the knee is swung outward until the sole of the foot rests squarely on the floor. The photograph will also illustrate the usual deformity after this kind of fracture.) The axis of the leg, prolonged downward, fell to the inner margin of the sole. There evidently had been a fracture of the internal malleolus at its base, and of the fibula, about three inches from its lower end; the angular deformity between the two fragments was marked, and is well shown in the photograph.

Union was firm and complete, motion at the ankle joint nearly normal, there being a slight diminution of flexion. The patient was anxious for any operation that would give him a useful leg, for in his present condition he could not attend to his usual work.

In looking up the case in such works as I then had at hand, I found in Dr. Stimson's work on *Fractures* that the following operations had been done for the relief of viciously united Pott's fractures:

I. Le Dentu refractured in a case of vicious union after Pott's fracture of three months' standing, using an osteo-elast. A solid plaster splint was applied and retained for six weeks.

*Result.*—A useful leg, with slight deviation outward, but the sole rested squarely on the ground.

II. Dr. Fenger, of Chicago, had operated on several cases by removing a wedge-shaped piece of bone from the tibia two inches above the internal malleolus. The base of the wedge was an inch wide and on the inside of the leg, the apex at the outside. The foot was brought into position after fracturing the fibula. The operations were said to be satisfactory, but full details of the condition of the joint were not given.

III. Dr. Stimson also states that he saw Dr. Sabine in 1881 operate for this deformity by dividing each bone with a chisel through separate incisions an inch above the base of the malleolus. He could then bring the foot into the axis of the leg without removing a wedge-shaped piece of bone. The patient made a good recovery. In commenting upon this operation, Dr. Stimson says that it meets only one indication; it brings the foot into line, but does not correct the separation of the malleoli, and it changes the direction of the articular surface of the tibia so that it faces inward instead of being horizontal.

IV. Excision of the ankle with various modifications

has been done. Ankylosis is aimed at and the results are more or less satisfactory.

None of the above operations was performed. The deformity was corrected by the following method, and three years of continuous use of the limb in heavy work attests its value. The aim was to *reproduce the original injury*. The operation was performed with strict attention to antisepsis, and under a continuous bichloride irrigation of 1 to 4,000. An incision an inch and a half long in the long axis of the fibula was made over the seat of fracture, and the bone divided by a chisel at this point. This allowed the foot to swing partially into place, its further inversion being blocked by the internal malleolus which had united to the tibia in a position of outward displacement (see Fig. 1). The base of the internal malleolus was next exposed through a vertical incision, the periosteum peeled up, and the chisel entered transversely at its base an inch and a quarter from its lower end, and driven obliquely into the joint, to come out at the angle of junction between the articular surface of the malleolus and tibia. This of course opened the joint, which was irrigated with the bichloride solution. The foot could now be fully inverted and the deformity reduced.

The periosteum and skin over the internal malleolus were separately sutured, a drain being omitted. The fibular wound was closed over a drain of a few strands of catgut. The foot was strongly inverted and flexed to a right angle with the leg and a heavy plaster-of-Paris splint applied over a thick antiseptic dressing. The foot was firmly held in position until the plaster had fully set.

The operation was performed on June 2d, and I might state here that while the patient was on the table it was noticed that he had a large hydrocele. This was first treated by Volkmann's open incision, and excision of a portion of the tunica vaginalis; in this case a strip two inches and a half by half an inch was

FIG. 1.

FIG. 2.

removed. The wound healed rapidly and the hydrocele has never returned.

*June 5th.*—The patient had a temperature of 103° F. Fenestræ were cut in the splint and the wounds examined. Internal one healed by primary union. Outer one showed retention of secretions; sutures were removed and wound packed.

On the tenth day the old splint was removed and a new one reapplied. Motion in ankle two thirds. On the twelfth day the

patient was out of bed. The case went rapidly on to recovery, a new plaster splint being put on on the nineteenth day.

*July 4th.*—The last plaster was removed. Wounds entirely healed. Full ankle motion.

*16th.*—Photograph No. II taken. The superficial ulcer shown in the photograph was due to the pressure of the plaster splint and soon healed. The swelling of the leg soon disappeared. With these changes the photograph would do to illustrate the present condition of the ankle.

*17th.*—Discharged cured.

The subsequent history is as follows:

The patient went home and to work; for about six months he wore an iron support to his ankle, an arrangement made by the village blacksmith, but he soon discarded this, and ever since has been doing the hardest kind of work without any ankle support, and states that he can work all day without fatigue or weakness in the ankle, and on Sundays, he says, in pleasant weather he walks from seven to fifteen miles for pleasure.

Present condition of the ankle: As above stated, the position of the foot is well illustrated by Fig. 2. There has been no outward deviation of the foot whatever. There is a slight thickening over the internal malleolus which makes the ankle look slightly wider than the other. Extension is perfect, flexion is resisted beyond a right angle, due to a slight shortening of the tendo Achillis, which will probably be overcome by use.

The operation here described for the relief of not too long standing cases of vicious union after Pott's fracture is a rational one. It aims to restore the limb to the condition it was in at the time of the injury, and then treat it as a case of recent fracture. To do this, the internal malleolus and fibula are divided at the seat of old fracture; the foot then is to be superinverted and flexed and this position maintained for four to six weeks by plaster-of-Paris dressing.

The operation is simple and practicable. It is less formidable than a cuneiform or linear osteotomy of the tibia above the malleolus and does what these do not do—namely, preserves the horizontal articular surface of the tibia and restores the mortise of the ankle to nearly its normal condition. For, though there may have been a gap between the tibia and fibula at the beginning, and this filled in with new tissue, by the pressure exerted upon this by the fibula when the foot is kept fully inverted for four or six weeks, we have reasonable assurance that the most of this tissue, if it be present, will be absorbed.

The final result is all that could be desired. Motion will probably be normal, the foot stand as much work as its fellow, and no tendency to a return of the deformity exist.

316 EAST EIGHTY-SIXTH STREET.

**The Secretion of Bile in Uræmia.**—"In order to elucidate the character of the secretion of bile in artificially induced uræmia, Dr. Lökianoff, of Warsaw, tied the ureters close to the bladder in twelve guinea-pigs, collecting the bile of six of these during the first day and of the remaining six during the second day of uræmia. He found, among other results, that uræmia tends to reduce the body temperature; as a rule, the liver increases in weight to a slight extent, the blood and the kidneys become richer and the liver and brain poorer in watery constituents, and the secretion of bile is rather less than normal. The production of hepatic tissue is diminished, especially as the uræmia progresses. The bile secreted is poorer in water and richer in solid matters than in the normal condition or in the first stage of starvation."—*Lancet*.

## SOME NASAL, THROAT, AND AURAL SYMPTOMS AND DISORDERS MET WITH IN INFLUENZA.\*

BY BEVERLEY ROBINSON, M. D.

CLINICAL PROFESSOR OF MEDICINE  
AT THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

ASIDE from the fact that the nasal, throat, and aural symptoms and disorders met with in influenza accompany general phenomena which establish their probable nature, we can not affirm that they are invariably characteristic or different from nasal, throat, and aural affections encountered separately and in no sense indicative of an infection of the entire system. Thus we may have a nasal catarrh in influenza, with sneezing, local irritation, heat, and obstruction, which resembles an acute coryza due to chilling of the surface or exposure following fatigue or the inhalation of foul air. Again, we may have an attack of pharyngeal inflammation or of acute amygdalitis, which wholly resembles these disorders when occasioned by ordinary causes, except for the accompanying symptoms of generalized pains, higher febrile reaction, and more bodily and mental depression than is usually produced by like local conditions under other circumstances. This is equally true of the forms of acute aural or laryngeal catarrh occurring during the course of influenza. But when this has been said we must add that there are occasionally some noticeable peculiarities about the affections referred to, and others still of the nose, ear, and throat, as observed in epidemic influenza.

In one very interesting case of influenza that I have treated, the initial stage of the disease was ushered in by repeated and profuse attacks of epistaxis requiring repeated plugging of the nasal passages in order to stop it. These nose-bleeds were especially interesting, because while there could be no doubt that they were in part due to intense venous turgidity of the pituitary membrane under the dependence of the general blood dyscrasia they were also accentuated and made much more serious by the rupture or ulceration of the septal artery in one nasal passage. It seemed possible that the latter source of hæmorrhage was developed by the act of picking the nose to remove a semi-hard blood clot, and the artery had been in part opened by the patient himself. The case was that of a lawyer of middle age, who, previous to the recurrent nasal hæmorrhages, had never suffered from nose-bleed or nasal catarrh, and who had always enjoyed remarkably good health. Immediately subsequent to the attacks of epistaxis he had the rational symptoms of severe influenza. During the course of this disease both the soft palate, fauces, and larynx were deeply congested. Indeed, the veins of the palate and fauces seemed so distended that I thought for a day or two that it was possible to have them rupture and bleed during the efforts of cough. The interior of the larynx was red and swollen, notably the ventricular bands. I could not, however, detect in this organ any distinctly marked ecchymotic areas or any characteristic venous dilatation.

\* Read before the Section in Laryngology and Rhinology of the New York Academy of Medicine, March 23, 1892.

In some late autopsies on influenza patients, very carefully reported by Helweg, it was noted that the pia mater and brain were extremely hyperæmic. It was also observed that the arteries of the base of the brain were distended to an excessive degree "and stood out as cylindrical cords, as if they had been injected with wax." This pathological condition, according to Althaus, is not due to a simple vaso-motor hyperæmia, but to a process which tends toward a real inflammatory state, which does occur in persons particularly disposed to it. (*Vide the Lancet*, February 13, 1892, p. 387.) In view of these statements, we can readily understand how profuse nasal hæmorrhage may take place as an intercurrent complication, either in the beginning or during the course of influenza.

The erythematous sore throat of influenza has seemed to me to be accompanied with and followed by more marked local pain in the throat than is noted in a sore throat apparently similar in nature when not dependent upon influenza. This form of sore throat sometimes extends upward, producing considerable irritation and obstruction of the naso-pharyngeal space, as shown by the local distress and the difficulty of free nasal respiration. The latter is especially aggravated at night when the patient lies down, owing to the tendency of the blood to fill up the distended posterior extremities of the turbinated bodies. It is in these instances, even without the nasal occlusion, that we are apt to observe an extension of the catarrhal inflammation to the Eustachian tubes and to the middle ear, which is followed by pain in the ears, impaired hearing, tinnitus, and dullness of the mental faculties.

The membrana tympani may become thickened and sunken, and effused mucus and fibrin may be thrown out around the ossicles and their articulations, which ultimately leads to partial ankylosis and permanent deficient hearing. Occasionally the nasal catarrh, with occlusion of the nasal passages, precedes the faucial irritation, and in more than one instance closely observed by myself the sensitiveness of the peripheral nerves of the pituitary membrane was very considerable, so that the slightest contact with a foreign body of certain limited areas caused intense suffering, which, however, disappeared as soon as this contact was broken. On other occasions I have observed follicular amygdalitis adjoined to phenomena of acute gastric catarrh and characterized by excessive stomachal intolerance, so as to cause the rejection of nearly all food and medicine for a day or two. The follicular amygdalitis cleared up in less time than usual, and fewer follicular deposits were visible at any one time than is habitual.

There was a tendency to repetition, however, of the follicular deposits, and there were occasionally very severe paroxysms of pain in the tonsillar region, which returned with well-marked periodicity.

I have known the tonsils also to become suddenly very much enlarged and occasion very great obstruction of the breathing. In this case, that of a child nearly three years old, there was no follicular deposit on the tonsils, but their enlargement was quickly followed by the perforation of one, and twelve hours later of the other membrana tympani. Both ears were affected with quite abundant suppuration

for many days. As is sometimes observed in scarlatina and other febrile disorders, the perforation of the drum membrane of the ear was preceded by relatively slight pain, and even this pain lasted but a short time before the perforation occurred.

This statement I regard as important for the following reasons: One is often blamed by parents or patients for the occurrence of a perforation which was practically unavoidable. Besides, the reproach which might be made that we had not instituted sufficiently careful measures to prevent it is not merited, because neither the time nor the symptoms would indicate the necessity of too much local interference.

Finally, it may be observed that the perforation of the membrana tympani, if it takes place early and without much pain, is perhaps properly estimated as a conservative and judicious effort of Nature to prevent further and more injurious destruction of aural structure. It is true, at any rate, and most fortunately, that many such cases, if regularly douched and cleaned, get well before many weeks have elapsed, and with retention of very good, if not absolutely normal, hearing. Of course there are many unfortunate and pitiable cases, but these occur mainly among victims of ignorance, neglect, and of already depraved constitutions.

In writing on the effects of influenza on the middle ear, Sir William Dalby (*vide Lancet*, Feb. 20, 1892, p. 416) says that in his experience suppurative complications are infrequent. Besides, he states that this disease rarely attacks healthy ears, even in the form of *non-purulent catarrh* with obstruction of the Eustachian tubes. What this distinguished aurist has particularly noted is the fact that patients who formerly suffered from purulent median otitis, and whose ears have been in a quiescent state perhaps for several years, again suffer from otorrhœa owing to an attack of influenza. And to this statement he adds what he considers as apparently showing the influence of the general disease, that the condition of the ears previously had been good, "notwithstanding ordinary colds and exposure to all sorts of variations in climate." "Thus," he continues, "a person with healthy ears has little to dread from influenza so far as this mucous surface" (referring, of course, to that which lines the middle ear) "is concerned, but it may become a serious trouble to one whose ears have formerly been the seat of inflammation."

I am scarcely in accord with this latter affirmation, since, as a matter of fact, the aural complications I have had to care for have usually occurred in ears previously healthy, or, at all events, which never before caused any rational symptoms indicating aural disease.

I would, of course, consider my observations less important were I not in a position to see many cases which ordinarily seek aid from a professed specialist for the treatment of diseased ears. In one patient whom I took care of this winter, the attack began with generalized pains in the head, body, and limbs, some mental hebetude, marked prostration of the forces, and considerable febrile reaction. The following day, in the morning, the pains had diminished, except those located in the chest anteriorly, which were intense. I auscultated the patient carefully, but could find no

signs of either pneumonia or pleurisy. The chest pains appeared to be of myalgic character. During the afternoon the patient expectorated repeatedly small quantities of dark blood which apparently came from the larynx or trachea. The stethoscopic signs in the chest still remained negative. I made a laryngoscopic examination, but, on account of the patient's intolerance of the mirror, I was unable to determine whether or no there were any ecchymotic spots in the larynx. The soft palate, however, was very much congested, and in two places there were hæmorrhagic areas, bright red in color, underlying the mucous membrane. Both of these areas were at least one fourth of an inch in length and two or three lines in width. No other hæmorrhagic spots were seen in the throat, nor were any petechiæ remarked on the cutaneous surface.

In this instance, if I had been able to make a satisfactory laryngoscopic examination, I would have doubtless discovered ecchymotic areas in the larynx and upper portion of the trachea. I am justified in this belief by the reported cases of Moure and other observers abroad, and in view of the history of my own patient.

Occasionally there is very little or no irritation or inflammation of either nose or fauces, at least in the beginning, but the laryngeal catarrh is most pronounced. Usually the laryngitis is not exclusively localized, but the inflammatory condition extends more or less to the trachea and bronchi. Whenever there is very considerable cough, due apparently to a laryngitis, it is wise to inspect the larynx with the small mirror. Oftentimes we shall find redness and slight thickening of a portion or the whole interior of the larynx. Now and then the patient's throat is so sensitive, and gagging so easily produced, that our examination is necessarily short and imperfect.

In the laryngitis of influenza there is not the amount of local soreness, hoarseness, or pain on swallowing, which we expect to find when the ocular appearances reveal so much local inflammation.

I have never observed within the larynx either the ulcerations, pronounced œdema, or the membranous deposits which have been noted in Europe. Singular to say, at times when there has been a most rebellious and painful cough, and when the larynx seemed especially affected, the local signs of the inflammation were very slight. Indeed, the true vocal cords were seen to be almost of normal coloration. In these instances particularly the cough was harassing, paroxysmal, often dry, with frequently a prolonged noisy inspiration at the end, which resembled the "whoop" in pertussis, and was obviously due to laryngeal spasm.

All general remedies fail in these cases to relieve; and, on the other hand, I have known an intralaryngeal application of iron, or some other ordinary astringent, to be evidently useful in diminishing paroxysms of cough. I could explain such examples only by assuming that I had to do with peripheral nerve irritation (neuritis?) in the larynx, very similar in nature to that met with in many other organs of the body.

On one occasion, when there was very intense gastric catarrh, shown by numerous symptoms, the regular system-

atic exhibition of milk and old brandy appeared to relieve intense paroxysms of cough, and even though there was present at the same time a great deal of bronchial catarrh.

I have little doubt in my own mind at present that a depressed state of the nervous centers is also an additional and efficient cause of more frequent cough, by reason of the increased impressibility that this condition gives to all inflamed nerve filaments. In this way I can appreciate how fatigue, lack of food, emotional strain of any kind during influenza, will immediately augment and intensify cough. I would add, however, that I have been much impressed during the prevailing epidemic, as I have been at times previously in other general acute affections, that local artificial irritations within the larynx will often relieve cough, when one, aside from this fact, might find sufficient cause for cough in the bronchial catarrh.

I rather believe, therefore, that, except for the supersensitiveness of the laryngeal mucous membrane, much sputum would remain many hours at times in the bronchial tract without being coughed up and expectorated. The distressing, recurrent paroxysmal, almost dry cough of influenza may last for many weeks, and resist all remedial influences for its cure, except, perhaps, complete change of air and scene. This affirmation is made in view of my experience, and of having tried uselessly all rational methods of relief.

In this connection I would direct attention to (*vide* Prosser James, *Lancet* of February 27, 1892, p. 498) some laryngeal affections occurring after influenza. Among them may be particularly noted paralyses, commencing in the throat after convalescence, and extending later to other regions of the body. These instances are of such a character as to simulate the paralyses taking place after diphtheria, and to have led more than once to a reasonable doubt being evinced in regard to the correctness of the original diagnosis of influenza. Other paralyses more localized than the former have come on after the patients had returned to their ordinary vocations. In this number are described paralyses of the tensors and adductors of the vocal cords. Neuroses of sensation as well as neuroses of motility have been observed, and different degrees of anæsthesia or hyperæsthesia are not infrequent.

Choreic movements and spasmodic conditions affecting the larynx are rare and late sequelæ. It would appear, according to James, that "these cases of late sequelæ are indications that the effects of influenza remain for a considerable period, and the proportion of neuroses shows how profoundly the disease affects the nervous system."

In one instance I have seen a very sudden inflammation in the muscles of the neck, which was accompanied with pain, redness, and rigidity, and so much localized heat that I feared abscess during twenty-four hours. The latter symptom—viz., heat—quickly subsided under soothing applications, but the pain and stiffness of the neck lasted nearly a week.

In this patient there was no complicating sore throat. In another patient now under observation the neck is stiff and painful, and there is also present an erythematous sore throat.

I have tried many of the drugs which have been recommended during the present epidemic. The following combination has appeared to me at once the most reasonable and the most successful. The prescription, made up in tablet form by Mr. Fraser, pharmacist, of this city, is as follows: Half a grain of citrate of caffeine, one grain of phenacetine, and three grains of ammonium salicylate. I order one of these to be taken every hour, every two hours, every three hours, according to the amount of pain, depression, and general disturbance which are observed during the attack. In addition, I make use of such local or other treatment, adjoined to rest, protection from cold, and proper nutriment, as I may deem advisable. The formula made use of by me is extremely rational; the caffeine stimulates the heart and promotes elimination through the kidneys; phenacetine, in small, repeated doses, diminishes pain and fever and promotes perspiration, thus making use of another great emunctory of the economy—viz., the skin; the salicylate of ammonium agrees with the stomach. By the use of salicylic acid, I employ a well-authorized anti-microbial, anti-zymotic agent. With ammonia set free in the stomach, I give an alkaline remedy, but one that is not depressing, as the salts of potash undoubtedly are. And this sort of medication is specially essential, even in large, repeated doses, as witness the statement made by English practitioners of repute during the present epidemic, and referred to interrogatively, but with some belief on account of the testimony in its favor, in an interesting editorial in the *Lancet*, only a few weeks since.

Of course I vary my combination in certain instances, and at times leave out one or other of the ingredients, according to the circumstances of the case. Again, I have treated certain forms of disease which I have believed were caused by influenza, or, indeed, were unusual or aborted manifestations of it, in which I have not made use at all of my compound salicylate tablets. The specific treatment of influenza has not yet been found, and perhaps may not be found for many years to come; still, such a discovery is not impossible, and some fortunate searcher in our art may yet happily light upon it almost unawares. Meanwhile the suitable medication to employ is that which united experience tells us is the most rational and successful.

In regard to local medication for cough and bronchial catarrh, I would add that after using steam inhalations with turpentine and benzoin in the initial stages of influenza, I have found dry pine-needle oil vapors, used persistently and frequently with the perforated zinc inhaler, worthy of especial commendation and real confidence.

In the way of prophylaxis, there is one precautionary measure which may be utilized by every one and which apparently has its value—viz., occasional gargling the mouth and throat with an appropriate antiseptic solution. In this connection I have permission to cite the following lines taken from a personal letter to me, received on January 26, 1892, from Dr. Charles A. Siegfried, Surgeon in the United States Navy, now stationed at Newport, R. I. Dr. Siegfried writes: "I am convinced that gripe can be pretty nearly prevented by keeping the mouth and throat clear and well policed with an alkaline carbolated lotion twice or thrice

daily. Those of my friends (including myself) who have followed this plan have escaped. I suppose you have noticed the alkaline treatment of Dr. Crerar in the *Lancet* and the discovery of Pfeiffer, who finds the bacillus in the mouth, so that, theoretically, I am on the safe side." It may be wisely added to this statement, I believe, that possibly this precautionary measure for those who have hitherto escaped taking influenza may be also a useful recommendation to those already affected, toward diminishing its severity and warding off the complications (pleuritis, pneumonia, otitis media, affections of the eye, etc.) by destroying the virulence of the influenza bacillus at the gate of entrance into the system. In this manner may be prevented the constant reinoculation of the body by continuous absorption of the materies morbi—bacillus or habitat of the bacillus, as the case may be. We recognize to-day the great advantage of frequent local disinfection of the mouth and throat in diminishing the gravity of diphtheria. Why may it not also be true of influenza and some other general acute febrile disorders, at least somewhat analogous in type?

In concluding this contribution, I would add that I have not attempted to make it exhaustive, although I have quoted several times from the work of foreign writers. My article is essentially based upon what I myself have observed during the past two winters, and as such I offer it for discussion.

## PAIN,

ITS NATURE, DIAGNOSTIC SIGNIFICANCE, AND TREATMENT.\*

BY J. LEONARD CORNING, M. D.

THE relief of suffering is the distinctive prerogative of the physician. It is doubtless this ability to bid defiance to pain which, more than any other single attribute, has enabled medical men to maintain, in spite of the vicissitudes of therapeutics, such a high position in the estimation of society. Some of the most famous lights of the profession have in all ages been imbued with this great fact. The neurologist, more especially, should be thoroughly conversant with all matters pertaining to pain, and particularly to the treatment of pain, for there is no single symptom which is liable to be more frequently met with, or whose elimination will make such stringent demands upon the practical resources of the art.

I shall offer, therefore, no apology for the following observations on the nature and treatment of pain, which, I trust, may prove of benefit to the physician in solving many of the practical problems of his calling.

*Physiology.*—The first question which naturally suggests itself is, How do painful impressions reach the higher centers of the brain, or, in other words, along what paths do such impressions travel in their journey from the periphery to the centers of conscious perception?

It is much to be regretted that only a partial answer can be given to this important question.

About all we know of it is soon told. In the first

\* Read before the Medical Society of the State of New York at its eighty-sixth annual meeting.

place, the transmission of painful sensations from the periphery to the spinal cord is accomplished through the instrumentality of the sensory nerves. The course pursued by such painful impressions through the cord is more obscure. Some physiologists believe that they are transmitted wholly through the gray substance; others, again, assign special importance in this connection to the sensory conducting paths of the posterior columns; while a third class of observers believe that sensations of pain may be transmitted both through the gray substance and the white substance (posterior columns). The attempt to associate the lateral columns with the conduction of sensory impressions must be regarded as premature, to say the least, in the present state of evidence. As regards the subsequent path pursued by painful impressions, it may be stated that various facts point to certain of the fibers of the posterior division of the internal capsule as those largely concerned in the transmission of such sensations to the cerebral cortex.

*Identity of the Processes in Motor and Sensory Nerves.*—It has often been asked, as a matter of theoretic interest, whether the processes accomplished in a motor nerve differ radically from those occurring in a sensory nerve. On this point Radcliffe, in concluding an elaborate argument, observes that "there is reason to believe that there is no essential difference between the action which issues in sensations and the action which issues in muscular contraction." As a corollary to this proposition, he adds that "the production of sensation and the production of muscular contraction only differ in this: that the electrical discharge, analogous to that of the torpedo, which is developed in and near the nerve in the state of nervous action, happens to tell upon sensorial ganglionic cells in the one case and upon muscular fibers in the other."

Of course, to speak of the electricity evolved during the action of a nerve as that mode of nerve force concerned in the production of sensation or motion is a mistake. In other respects the figure is an apt one.

It may be of interest in this connection to consider the experiments which had led Radcliffe and others to these conclusions. Undoubtedly the researches of Du Bois-Reymond and Matteucci have had a powerful influence in shaping opinion on this point. The principal experiment of Du Bois-Reymond consists in pouring hot water upon the leg of a frog, the nerve of the same being connected with a galvanometer. When this is done, the galvanometer shows a cessation of the electric current—a phenomenon which is observed almost as soon as the water touches the integument. This observation, in conjunction with the well-known fact that there is also a decrease, amounting sometimes to almost entire absence, of "natural electricity" during the action of motor nerves, led Du Bois-Reymond to the inference that in sensitive as well as in motor nerves there is a loss of electricity when the nerves pass from rest into a state of action.

Matteucci's experiment, performed upon a rabbit, consisted in dissecting out the upper portion of the sciatic nerve and irritating it with the galvanic current. When the current was closed the animal screamed loudly, but when it was opened there was no sign of pain.

The resemblance of the phenomena evoked by the galvanic current in sensitive nerves to those caused by the same agent when applied to motor nerves has led to the inference that "the change in a sensory nerve when sensation is produced by the action of voltaic electricity, and the change in a motor nerve when muscular contraction is produced by the same means," are, as Radcliffe puts it, exact equivalents.

Such, then, are the principal facts which have been assumed to prove the identity of the processes underlying the actions of motor and sensory nerves. While, however, the relation of the two kinds of nerves to the galvanic current points to the truth of this proposition, it is, of course, self-evident that the *final result* of the action differs radically in each kind of nerve. In the case of the motor nerve, action results in contractions, due to the excitation of the contractile substance of the muscle; in the case of the sensory nerve, on the other hand, action is translated into sensation through the instrumentality of the central ganglionic apparatus in the cortex.

So much for the fundamental features of the argument.

*Inductive Evidence on the Genesis of Pain.*—Let us now consider a set of facts which will help us to frame a reasonable hypothesis concerning the nature and genesis of pain. In the first place, it must be remembered that a sensory nerve supplies a certain definite area of the body, and transmits to the brain only such impressions as emanate from the area. In other words, there is no physiological anastomosis, however much the fibers may interlace or run together. To prove this, it is only necessary to divide a sensory nerve and irritate its distal end, when we find that no sensation is perceived, thus demonstrating that there is no collateral communication whatsoever. As a matter of course, irritation of the proximal or central portion of the nerve—that part which is in connection with the nervous centers—gives rise to distinct sensation.

In the same way, if we divide the spinal cord of an animal transversely, so as to sever the sensory conducting paths and irritate the nerves which join the cord below the incision, no sensation will be perceived; but if we stimulate the nerves which enter the cord above the incision, we shall have every evidence that the sensation has been perceived. Precisely the same sort of phenomena may be observed in human beings who, by reason of injury or disease, have suffered a solution of the sensory conducting paths of the cord.

Another important fact is that an impression made upon any point in the course of a sensory nerve may be perceived by the mind as though it were made not only upon the point in question, but also upon the parts to which the fibers of the nerve are distributed. We have, therefore, under such circumstances, precisely the same effect as if the irritation were applied to the regions supplied by the branches of the nerve.

An explanation is thus afforded of the fact that when the sensibility of a part is abolished by compression or division of the nerve which supplies it, irritations of the central portion may still give rise to sensations which are felt as though they emanated from the parts below the point of interruption—*i. e.*, from the parts to which the peripheral

terminations of the nerve are distributed. Thus, when a nerve is divided for the cure of an intractable form of neuralgia, it sometimes happens that pain still persists. This is undoubtedly due to the fact that the division of the nerve has not been made near enough to the nervous centers to include the entire affected portion, and hence the continued irritation of the central portion causes pain, which, in accordance with the law under consideration, is felt as though it emanated from the peripheral parts of the nerve. Another illustration of the same thing is afforded by those paralyses in which the limbs are quite insensible to such external stimuli as pricking, pinching, and burning, and yet are believed by the patient to be the seat of severe pain. Still another example of erroneously referred pains is afforded by persons who have suffered amputation of a limb. When the divided nerves of the stump are inflamed, or otherwise irritated, nothing is more common than to hear the subject complain that he experiences pain which appears to be located in the part of the limb which has been removed.

Such facts as these might, on a superficial examination, lead one to suppose that there was little or no benefit to be anticipated from local therapeutic measures addressed to the affected nerve itself in cases of pain. It must be remembered, however, that by the aid of chemicals we are in many cases able not only to temporarily cut off the peripheral portion of an affected nerve from its central connections, but also to modify the abnormal condition of the nerve itself, thus effecting an abolition of pain which is often permanent. Pain due to rheumatic causes is commonly amenable to local measures, while that associated with certain forms of well-developed neuritis offers a less favorable field for this class of remedies.

*Definitions of Pain.*—Various attempts have been made to define pain. Cicero looked upon it as a disagreeable movement within the body, independent of the senses. According to others, it is a species of sensation which may emanate from both internal and external regions of the body, in which are distributed nerves whose office it is to transmit to the brain all impressions which they receive. Lavoisier calls it a disagreeable perception, originating from any lesion of the nerve fibers; Gabius regards it as a sensation which the mind would rather not experience (!), while Bilon is discontented with all definitions, and believes the word pain to be so universally descriptive in itself as to enable one to dispense with all definitions.\* More recent authors have, nevertheless, still persisted in further attempts to define it. Thus Valentin † perceives in pain "sensory impressions which, on account of their too great intensity, become disagreeable"; Wundt ‡ calls it "a feeling that accompanies all powerful or intense stimuli," while Eulenburg § defines it as "a gradual increase of the feeling that accompanies every sensory process."

\* *Dictionnaire des sciences médicales*, vol. x, p. 179, Paris, 1814.

† *Physiologische Pathologie der Nerven*, vol. i, p. 240.

‡ *Lehrbuch der Physiologie des Menschen*, p. 503, 1074.

§ *Functionelle Nervenkrankheiten*, p. 31. Vide also *Diseases of the Peripheral Cerebro-spinal Nerves*, by Wilhelm Heinrich Erb. *Von Ziemssen's Cyclopaedia*, vol. xl, p. 14.

To my mind, the views of Erb\* regarding the nature of pain are the most comprehensive and just which have been recently expressed. "We hold," he says, "that every increase of ordinary sensory stimuli is capable of producing pain as soon as it attains a certain intensity. Every excitation the intensity of which exceeds certain limits, every molecular change of the centripetal series induced by an abnormally strong stimulus, is perceived as pain. Very simple experiments—as, for example, pressure or temperature gradually increased till pain is produced—show that with very gradual increase in the strength of the stimulus a limit is at length reached beyond which the excitatory process is accompanied by pain, yet no sharp line of demarcation can be traced defining the point at which the sensation of pressure or temperature ceases and the sensation of pain commences. The simplest explanation accordingly seems to be that pain is the reaction of the sensorium to a certain degree of excitation, and we at present see no ground for regarding pathological pain as being essentially different in origin from that which can be produced by simple physiological experiment."

We thus find a clew to the genesis not only of those pains which originate in over-stimulation of the nerves of common sensation, with which we are most frequently called upon to deal, but of those, likewise, which have their origin in an exaggerated stimulation of the nerves of special sense. For do we not know that intense light and loud, inharmonious noises produce sensations which are described by those subjected to them as veritable pains?

As regards the nature of those fine molecular perturbations originating in the nerve and transmitted thence to the sensorium—perturbations which are evidently the essential accompaniment of pain—we are still, and doubtless are destined in future to remain, entirely in the dark. Although we are thus debarred, on account of the erudition of our physiology, from penetrating the ultimate mystery of pain, we are, nevertheless, enabled to adopt proper means for the arrest of the morbid irritation in the nerve, when once established. As the argument proceeds, we shall find that in combating pain we are compelled to invoke the aid of a wide range of agents; and thus it happens that chemistry, thermodynamics, physics, and even surgery, have all rendered important assistance.

Finally, we must not forget to mention a very recent theory regarding the mechanism underlying the pains found along the course of nerves. According to Prus, † who is the promulgator of this theory, there are filaments in the sheaths of nerve trunks the irritation of which gives rise to the painful points found in neuralgic affections. These filaments, the presence of which was made known by careful microscopical examination, have received the somewhat ponderous appellation of *nervi nervorum periphericorum*.

It is, of course, impossible at present to prophesy with any degree of certainty what part these structures are destined to play in the physiology and pathology of the future.

\* *Op. et loc. cit.*

† *Archives slaves de biologie*, iv, September 2, 1892. See, also, *Brain*, vol. x, p. 557.

Perhaps autopsies conducted with a special view to our enlightenment on this point may afford information; but it is hardly to be anticipated that we shall derive much help from experimentation.

It now remains to say something in regard to the causation of pain. It may be stated at once, in this connection, that by far the most prolific source of the perverted sensation is found in the condition of the nerve known as neuritis. The two principal types of neuritis are simple neuritis and multiple neuritis. Under the last-named heading are comprised the conditions known as alcoholic neuritis, neuritis of leprosy, and that of beriberi; the two last-named conditions are so rare in this country as to merit rather a pathological than a clinical interest. Simple neuritis and multiple neuritis, on the contrary, are exceedingly important phases of the affection, since they are of frequent occurrence, both in hospital, special, and general practice. As its name implies, simple neuritis is simply a local manifestation of the disease, the inflammatory process being restricted to one or more nerve stems.

The most frequent causes of this form of neuritis are wounds, inflammatory conditions in the vicinity of the nerve-stems, rheumatic influences culminating in thickening of the sheath, and tumors pressing upon the nerves. Severe compression of the nerve, caries of neighboring bones, and bruises may also give rise to it. To sum up the whole question of aetiology, it may be stated that the restricted form of neuritis is more apt to be due to local than general causes, while of multiple or general neural inflammations the reverse is true; for toxic agents, acting more or less extensively throughout the organism, play a prominent part in their causation.

In multiple neuritis, as previously noted, we have to do with a symmetrical and more or less widely disseminated inflammation or degeneration of the sensory or motor nerves. As a rule, the cerebral or bulbar nerves are little or but slightly affected.

Since Dumenil published his excellent paper in 1864 a multitude of observers in this field have come forward; and, indeed, hardly a year goes by without witnessing extensive additions to the literature of the subject. At the present time the available material is quite overwhelming, so that detailed references to it would, in a short paper of this kind, only serve to add confusion to a subject already sufficiently intricate.

I shall confine myself, therefore, to the most general observations. Let me begin with a few words in reference to the aetiology of multiple neuritis. As has already been said, the most common causes of multiple neuritis are toxic and infectious agents. In this category belong lead, alcohol, illuminating gas, bisulphide of carbon, arsenic, aniline, dinitro-benzine, phosphorus, mercury, morphine, ergot; and among animal and endogenous poisons of various kinds, fevers, diphtheria, tuberculosis, beriberi, leprosy, malaria, gont, rheumatism, diabetes, and the puerperal condition. In addition to these, dyscrasic states undoubtedly play a part in the evolution of certain phases of the disease.

Here we have the explanation of those cases of neuritis

which occur in the course of affections involving more or less impairment of the physiological integrity of the bloodstream—marasmus, chlorosis, and cancer.

A large proportion of cases begin acutely, a small number develop more gradually, while a third class displays great lethargy in the evolution of the different symptoms.

Hence it is customary in some of the books to describe an acute, a subacute, and a chronic form of the disease. The general symptoms of multiple neuritis are about as follows: In a large proportion of cases the symptoms begin abruptly. It is true that the patient may complain for some days of vague feelings of malaise and weakness in the lower limbs, but these sensations commonly excite little or no attention, and not until more definite symptoms are added is medical aid invoked. At this time he suffers from vague discomfort in the head, loss of appetite, and mental hebetude, and he may even be delirious. There may also be considerable fever, the temperature reaching 101° or even 105°, while the pulse is correspondingly accelerated. Sometimes, however, the evolution of the symptoms, even in the beginning, is more gradual, and it is then quite difficult to predict what is really impending. Whatever phase these premonitory phenomena may assume, however, they are certain, or almost certain, to be speedily followed by symptoms of sensory irritation. The subject complains of tingling, numbness, crawling sensations, and pain. These symptoms are specially pronounced in the affected limbs, but they evince, as may readily be imagined, a decided predilection for the regions in the vicinity of the nerves. While sensory irritation is apparent from the beginning, the opposite condition of sensory paralysis is by no means so obvious. It is true that the muscular sense may be so impaired as to give rise to pronounced ataxia; the tactile nerves, too, may be more or less affected, and the transmission of sensations of heat and cold, as well as those of pain, may be considerably retarded. Still, it must be borne in mind that when the sensations reach the central perceptive mechanism they possess considerable vigor, and are, therefore, felt with great distinctness. Complete anæsthesia, then, is decidedly exceptional. The distribution of these paræsthesiæ is a matter of some interest. Sometimes they are associated with the ramifications of a particular nerve, while at others they are distributed in irregular islands without obvious physiological connection; or, finally, they may pervade the entire limb. In any event, their presence is significant and often of the first importance in forming a correct diagnosis.

The pains, too, when taken in conjunction with the other features of the case, are of value in forming an opinion as to the nature of the disease. Though somewhat like those of locomotor ataxia, they differ notably in this: that whereas in multiple neuritis the pains are readily evoked by pressure upon the nerves, this is not usually the case in ataxia. With the advent of these pains there is sometimes more or less œdema, profuse diaphoresis, or swelling of the joints; this is specially true of the epidemic variety of neuritis. The last-named symptom has frequently caused the case to be mistaken for acute articular rheumatism.

Not less important than the sensory symptoms are the

derangements of motility. The latter, unlike the former, are non-irritant in type, paralysis of motion being the rule, while spasms are rare. In the majority of cases the paralysis begins first in one leg, speedily involves the other, and may advance thence to one or both arms. As a rule, the invasion is rapid, the loss of power beginning as a simple sensation of weakness on standing or walking and culminating in more or less complete paralysis in fifteen or eighteen days. The distribution of the paralysis presents some points of interest. In the first place, it is a remarkable fact that the muscles which actuate the small joints of the hands and feet and the wrists and ankles are much more affected than those of the elbows and knees. Thus, in a case which I recently saw in consultation with Dr. Haines, of Newark, the patient, a man of sixty, who was a sufferer from multiple neuritis of malarial origin, was able to move both elbows and knees without difficulty, while voluntary motion in the wrists and ankles was quite impossible. Another interesting point is, that the paralysis shows quite an irregular distribution at first, but assumes the characteristic form when fully developed. I emphasize this point because on seeing the case at the commencement of the paralytic invasion one is apt to be puzzled unless forewarned of the erratic character of the symptoms. Such, then, is the more common course of general neuritis—a course which, as previously intimated, is subject to considerable variation.

Time does not, however, permit our consideration of the erratic types of the disease.

*Simple Neuritis.*—The duration and course of simple neuritis are subject to a certain degree of variation. Usually, however, the onset is quite abrupt, although a gradual beginning is occasionally observed. Moreover, an initiatory chill and fever occur in some cases, but the majority begin without these warnings.

Whatever the precise mode of onset may chance to be, the first symptom to excite the apprehension is the pain. This pain is usually severe and is felt more or less throughout the distribution of the affected nerve. On applying gentle pressure along the course of the nerve, the latter is found to be extremely sensitive; and after the trouble has lasted a certain amount of time, it is often possible to feel the nerve (which has become considerably thickened through the integument). Though the pain is more or less persistent, it sometimes abates, but only to return again with renewed intensity. I have under my care at this time a patient in whom the intermittent and severe type of neuritic pain is well illustrated. The patient, a lady of remarkable intellectual gifts, was recently referred to me by Dr. M. S. Ayers, of Fairview.

Disturbances of sensibility and motility also occur in the simple form of neuritis, as well as in the more general type of the affection. Tingling, numbness, and a moderate degree of anaesthesia are observed in cases of medium severity, while in those characterized by more profound and permanent changes in the nerve the anaesthesia may be intense.

The motor derangements are sometimes merely of moderate extent, so that nothing more may be complained of

than slight weakness; but when the mischief is more serious, conduction is abolished, the implicated muscles are paralyzed and atrophy more or less extensively. If an examination be made by the aid of the electrical current at this time, the muscles will be found to exhibit the characteristic reaction of degeneration.

Finally, more or less extensive changes in the skin have been observed in a certain number of cases. The most common are vascular and herpetic eruptions; both the hair and nails may be involved, the former becoming brittle and the latter stubby.

*Pathology.*—When the course of the disease is acute the pathological changes are proportionately vehement. The affected nerve is seen to be reddened, swollen, and thickened; its vessels are distended and intensely hyperaemic, to which circumstance the lividity is due; there is a transudation of cellular elements and fluid from the engorged vessels into the interstitial tissue and nerve sheaths, and, in short, we have a typical picture of acute inflammation. On examining the condition of the nerve fibers more closely, by the aid of good lenses, we find that the destructive process is by no means as far advanced in some as in others. In those which present the most marked changes the axis cylinder is completely obliterated, the medullary substance undergoes fatty or granular degeneration, and the sheaths themselves are more or less completely disintegrated. Finally, the disorganized remnants may be more or less completely absorbed, and then nothing remains behind but the empty sheaths. This, as previously mentioned, is the course of events in the more severe cases; in those of a milder type, however, the changes are less far-reaching, nothing more than moderate swelling of the sheath and granulation of the medullary substance being discoverable.

Finally, cases which begin in a chronic manner do not present the primary stage of engorgement of the vessels and fluid and cellular infiltration.

It has already been noted, in the clinical portion of this chapter, that some cases of a severer type get well without loss of motility, provided the muscular atrophy has not been too extensive. This fact presupposes that the regenerative capacity of the nerves is prodigious. Considerable difference of opinion exists among pathologists as to the manner in which this restoration of the nerve filaments takes place. Of late, however, two theories have chiefly claimed attention; according to the one, new axis cylinders are evolved and prolonged from those which have escaped the ravages of the inflammation, while the other affirms that the young nerve fibers are derived "from an endogenous growth of nuclei within Schwann's sheath." Benets and Newman are adherents of this hypothesis.

In connection with the traumatic varieties of neuritis, the facts bearing on the regeneration of divided nerves are most interesting; for, from what has been learned, both experimentally and in the clinic, it is certain that more or less perfect union and restoration of function may be obtained in nerves thus mutilated.

Gluck found, in the course of a series of experiments on fowls, that the excision of a piece of nerve was not followed

by restoration of function, but that, after simple division, such restoration readily took place when the ends were carefully coaptated. This renewal of conduction was, moreover, established with marvelous rapidity—in two instances in twenty-four hours. As a rule, however, when the sciatic was divided and the ends subsequently joined with sutures, paralysis of the muscles supplied by the nerve persisted for fifty hours. After the lapse of this interval there was a gradual resumption of motion in the affected muscles, more or less complete recovery taking place in about four days.

Waller and Vaulair believe that the regeneration takes place from the central portion of the divided nerve, and that the peripheral end degenerates. Tizzoni, on the other hand, holds that the degeneration affects both ends of the nerve at the point of incision.

Eichhorst and Wagner maintain that the reorganization takes place from the nerve fibers on both sides of the incision, the new connecting fibers being derived from the axis cylinders.

Ranvier has indicated the important part played by the mechanical support of the tissues in maintaining the physiological distribution of regenerated nerves.

Lastly, Paget has found that, after division of the median nerve, sensation began to appear in the regions supplied by it within two weeks. Recovery was practically complete in about four weeks. As has already been said, the nature of the divided nerve favors cicatrization and regeneration of the peripheral ends, and hence the frequency and success with which the process has been resorted to by modern surgeons.

From the foregoing data it is evident that considerable difference of opinion exists among pathologists regarding the remarkable series of events which culminate in the restoration of function in a nerve previously injured either by the knife or the inroads of active inflammation. Nevertheless, many of the phenomena observed are exceedingly suggestive, and it is, moreover, highly probable that some at least of the points in dispute will be definitely settled in the near future.

*The Treatment of Pain.*—From what has already been said regarding the causation and conduction of painful sensations, it is evident that a wide range of remedies are applicable in treatment. In the first place, we may address our endeavors to the nerve itself, and strive, by the application of appropriate agents, to arrest the propagation of the painful sensations toward the sensorium; or we may seek to allay the inflammatory condition in the nerve itself. This we may do by localizing remedies in the painful districts\* by the application of ointments, by endermic medication, or, when all else fails, by division of the affected nerve stem.

But the mere alleviation of pain, though eminently worthy, is by no means the ultimate end to be desired. We should strive by every means in our power to effect a per-

manent cure. From what has been said regarding the causation of neuritis, it is clear that, in a large proportion of cases, the solution of this problem involves nothing less than the elimination from the system of some poisonous influence, such as malaria, lead intoxication, or syphilis, or the correction of some constitutional dyscrasia. Where the cause is found in some organic disease which serves to perpetuate the neuritic condition of the nerve, little can be hoped for from chemical agents of any kind. Under these circumstances we must address ourselves to surgery, that most useful art, which has done so much for the alleviation of human suffering. Unfortunately, as we have said, there are many lesions of the central nervous system which are quite inoperable. In this category belong the sclerotic and degenerative diseases of the brain and spinal cord. The most that we can do in such cases is to seek to render the patient's condition tolerable by the administration of analgesics and opiates. I will merely add, in conclusion, that when these agents have lost their potency, except when given in toxic doses, their physiological influence may be re-established by giving them while the patient is exposed to the influence of a condensed atmosphere, as I have recently shown in an article published in the *Medical Record* for August 29, 1891.

The time at my disposal does not admit of an extended reference to the philosophical questions underlying this mode of treatment; that has already been done in the article above referred to. I shall therefore merely state that this system of using compressed air in conjunction with drugs is based upon facts which I have succeeded in establishing by researches that fulfill the exigencies of the most exact induction.\*

From what has previously been said regarding the causation of neuritis, it is evident that anomalous conditions of the renal secretions, or at least some of them, bear a definite causal relation to the genesis of pain. Hence it follows that the correction of renal derangements, in so far as they are remediable, should always be undertaken as soon as they are detected. These observations apply with especial force to lithæmic conditions, which are but too often entirely overlooked.

53 WEST THIRTY-EIGHTH STREET.

## THE CHOICE OF CLIMATIC RESORTS FOR TUBERCULAR PATIENTS.

BY KARL VON RUCK, B. S., M. D.,  
ASHEVILLE, N. C.

At the recent Congress of American Physicians and Surgeons the discussion of this subject brought out the statement that, in addition to meteorological reports, the profession wanted more and other information than that furnished heretofore. The desire was expressed that the physicians practicing at climatic resorts should give their clini-

\* For some of the author's more noteworthy contributions to this field see the *New York Medical Journal* for December 26, 1891; the *Medical Record* for March 19, 1887; and *A Treatise on Headache and Neuralgia*, New York, E. B. Treat, 1888 (also subsequent editions).

\* The Use of Compressed Air in Conjunction with Medicinal Solutions in the Treatment of Nervous and Mental Affections, being a New System of Cerebro-spinal Therapeutics. The *Medical Record* of August 29, 1891.

cal experience, and tell the profession what particular class of patients derive the greatest benefit at the particular locality, and what stages, phases, and manifestations of the disease were most amenable to the influence of the particular climate; the profession caring less for information upon temperature, humidity, rainfall, and other meteorological data, and more for definite knowledge as to where the individual case would find the climatic conditions under which he would make the greatest improvement, and eventually a recovery.

This at first thought would seem an extremely reasonable demand, and if climatic treatment would necessarily lead to improvement and recovery (if only the right spot were chosen) the desired information would have come forth long ago.

Until physicians who advise phthisical patients will take years of time and, during a prolonged residence at each of these resorts, make personal and exact scientific as well as clinical observations to enable them to personally judge of the relative merits of climatic resorts, just so long will the profession have to depend for their information upon those members who practice at such health stations.

A week's or a month's sojourn by a physician at a climatic resort is entirely too short a time to gather the desired information—indeed, the grossest errors are possible from the impression so received by the individual—and for practical observation of patients suffering from a tedious disease like consumption, a much longer time would be required to make the conclusions of the observer of any value whatever, either to himself or to the profession, and it would take many years to so study the health resorts of the United States.

Physicians residing at health resorts are, however, supposed to have a personal interest in making their particular locality "come out on top," and the suspicion is not allayed with the observing reader when he notes in contributions to medical literature comparisons between one doctor's home-climate and that of many other places in which the argument and evidence adduced invariably go to show that this particular writer's climate is in every respect superior to every other; hence every patient should be sent there, if the home physician would do his whole duty to his patient! Such contributions, natural as they may be, constitute nothing but an advertisement, and should be relegated to the advertising pages of the journals in which they appear, even there to be judged for what they are—"a means for personal gain."

It is unfortunate, but can not be helped, that occasionally even scientific men will stoop to motives entirely unworthy, and never so good a climate does not seem to confer immunity from jealousy and selfishness.

This being the case, it is perhaps fortunate that the profession wants less knowledge of meteorological character and more clinical evidence, although meteorological data are entirely indispensable to a correct appreciation of any climate, even if they can not supply all information that seems necessary.

The late Dr. Brehmer, of the famous Goerbersdorf Sanitarium for Consumptives, in Germany, accorded such a

locality a curative influence in phthisis which could conclusively be shown to afford immunity from the disease to its inhabitants.

This theory commends itself to the good judgment of the student of phthiseotherapy, and will perhaps find more adherence than any other as long as our knowledge remains empirical, and particularly so inasmuch as such climates have been found valuable from a clinical standpoint also.

In a country like the United States, where reliable vital statistics are seldom made except in our large cities, and where many of the health resorts have been established in localities only recently or sparsely settled, it is difficult or impossible to apply this test; and, from the nature of the disease and its aetiology, it must ever be possible to show that the larger centers of population do furnish the greatest percentage of deaths from tuberculosis; it being also quite probable that a locality which can now show such a relative immunity as, for instance, is maintained by T. M. Lloyd (*New York Medical Journal*, April, 1887) and others for Asheville, N. C., and which the vital statistics of the city, kept now for four years past, seem to confirm, may eventually lose more or less of this favorable influence from an increase of population, as we now have in the older and more densely settled States. No one has, however, been able to explain what particular climatic condition produces such immunity, although many theories have been advanced.

In a recent contribution to the treatment of pulmonary tuberculosis, read before the Tri-State Medical Society at Chattanooga, Tenn. (The Treatment of Pulmonary Tuberculosis upon the Principles of Nutrition, *Dietetic Gazette*, November, 1891), I stated, as my conclusions regarding the effect of climate, that its mysterious influence disappeared if we looked upon it as it might affect the nutritive processes of the patients, and that a locality with much sunshine, and with absence of extremes of temperature, of strong winds and impurities and irritants in the air, but having a relatively dry and pure atmosphere, admitting of much out-of-door life, with sufficient elevation to favor a better circulation, must of necessity be better than where the reverse was the case, and reliable data by physicians or from other sources from our health resorts as to these conditions were certainly essential to the information of the profession.

If, now, residence in such a locality were all that is needed to enhance and favor the patient's nutritive processes, the information where this air can be found would be sufficient to guide the responsible home physician in his selection of a place, provided he has reliable data; but I am sure it requires no special mention that, no matter how favorable the climate, *on it alone* the patient's nutrition is not apt to thrive; and it is equally superfluous to mention that other conditions essential to the best nutrition of the patient may be so indifferent, or even bad, that not only will the climatic influence be unavailing, but in their presence the already impaired nutrition of the individual patient must of necessity seriously suffer in spite of the best climate in the world.

This means that apart from meteorological data the profession *is in want* of other information, and so important is this addition that without it the medical adviser can

foretell little of the result of his advice in the choice of climate.

To the meteorological data furnished the profession I am, perhaps, the only observer who has given attention to ozone for a number of years, and it would be very desirable if from other resorts similar reports were forthcoming. In addition, we need competent air and water analysis, both bacteriological and chemical, and I expect to continue in giving my attention to these additional subjects. Any one can see the importance of pure air and water, and nothing has been done in this direction at any of the resorts. We also need information upon the general hygienic conditions of the various resorts.

It is well understood that the so-called "mountain fevers" of elevated stations, said to be especially prevalent in Colorado, are, in fact, *typhoid*, and I have observed in Asheville that, as the hillside wells have been abandoned and as the sewer system is being extended, so have the "mountain fever" and summer diarrhœa diminished and disappeared.

To send a patient to a climatic resort, there to be exposed to the dangers of typhoid fever, would be a doubtful advantage, and one for which a relatively better air can not atone.

If at a given health resort the meteorological data appear satisfactory, the air nevertheless may be loaded with dust, impurities, and irritants of various kinds which the hygrometer, thermometer, and barometer do not indicate, and which would be seriously detrimental to lung and throat affections.

All such matters need to be known to the profession, and the information on these subjects needs to be reliable. The houses in which our patients live, their hygienic appointments and surroundings, their method of heating and ventilation, the cooking of and quality of food, the care and comforts offered, make not a little difference as to the results a patient may ultimately show when these are highly favorable or more or less unfavorable.

The kind of professional adviser into whose hands the patient falls, his skill, judgment, interest, and appreciation of the necessities of his patients, I presume make as much difference at the climatic resorts as at home; and I believe that if the patient can have the best of care and surroundings and perfect painstaking professional management at home, and has to do without most of these advantages at a climatic resort, he is better advised to stay at home.

Now, as to the clinical experience wanted, I would give the profession the following information, and it applies not only to Asheville, N. C., but to all health resorts, and in that respect it is fortunate that we can speak in general. The diagnoses are imperfect enough now, and it would certainly add much to the existing perplexities if it were necessary to diagnose with a view to the particular climatic resort to be employed.

So long as physicians will await the advent of serious symptoms and the latter stages of the disease before resorting to climatic treatment, just so long will they seek in vain for the especial climate that can uniformly benefit such patients.

If a patient is sent to a climatic resort, and he selects for his residence a boarding-house that stands on a thoroughfare, without grounds or piazzas, so that he is subjected to dust, noise, and annoyances of sundry kinds, and he can not be out of doors except upon the streets; if even slight exertion causes him shortness of breath, and he must climb two or three flights of steep stairs to his room; if the house is heated in the winter by stoves or fire-places and the halls are cold; if he is emaciated and must sleep on a hard bed; if he must go out of doors to water-closets in all kinds of weather; if he requires a judicious diet, but follows his own inclinations, or if, in the absence of a properly selected diet, he must eat tough meat, or pork and hominy cooked in grease; if he must wait upon himself, instead of having proper care and attention—then the patient has a poorer chance for improvement than if the conditions mentioned are as perfect as they can be made.

If a patient falls into the hands of a physician who advises long and tiresome walks, "to walk off" a temperature of 103°, as I know to have occurred; if he tells his patient: "Drink all the whisky you can," and the patient upon such advice succeeds in ruining his digestive organs; if the remedies for fever given by the medical adviser are drug antipyretics from one month's end to the other, and if for cough opiates are given as regularly; if this physician is one who follows routine methods, makes none or but superficial examinations, and keeps no records, or is not impressed with the great importance of details; if he does not understand or take pains in an individualizing management of each particular patient, with a view to prevent relapses and to keep the patient at his best all the time—then the patient's chances are diminished just to the extent that the professional management is deficient in these and other matters.

If the patient resides at a fashionable hotel and spends his time in the bar, billiard, card, or ball room, instead of out of doors or in quiet rest; if he eats mince pie, even if it should kill him, because he likes it, as a patient once told me he would; if ladies seek to excel others by elaborate toilets, and spend an hour each day in curling their hair, surely the chances of improvement are diminished by such trifling conduct, no matter how favorable the climate may be.

If a physician sends a patient, who is already much exhausted, upon a long, tedious, and tiresome journey to a health resort, that patient will, as a rule, be worse for his trip, and the conditions may then become such that the ease follows an unfavorable course to the end, in spite of any climate, especially if on arrival the patient is left to his own discretion.

The occurrence of acute inflammatory and destructive processes is favored or, if they are present, the symptoms are increased by overexertion and fatigue from any cause, and may continue to progress unfavorably until, by judicious treatment and management, an arrestment can be accomplished. The climate may aid in such arrestment, but it can not cut short at once this stage.

If a patient is sent who has already suffered destructive changes to a degree that large and, perhaps, suppurating cavities exist, and if, in addition, large areas of lung are in-

involved, embarrassed or inactive, if he is already suffering of amyloid or intestinal tubercular disease, if he is extremely emaciated from long-continued hectic fever, he will probably die soon after his arrival, no matter where and to whom he may be sent; the climate and the physicians at the place can not save him.

If a patient is sent even in the early stage with a view of staying a few weeks or months, and while at the climatic resort he is to have what is often called "a good time," by attending dances and elubs, mountain excursions and other frolics, probably he will suffer relapse, his disease extend, and he will then be likely to return to his medical adviser little benefited or even worse. Climate can not help it; it can not protect people from their follies.

If a patient is sent and his physician has led him to believe that all he needs is a change of air, that there is not much the matter with him, that he has only a little throat trouble, or that his lungs are a little weak, and if this patient suffers from tuberculosis in any stage, he will probably consult no physician until he relapses; if he does, and we caution him to the required conduct and care, he does not believe us, until more serious symptoms show that he is growing decidedly worse. Good results under such circumstances are not apt to follow, and such patients frequently return home with little or no improvement.

If a patient is sent who is well advised, both at home and at the resort, but who lacks that essential quality of manhood or womanhood, *self-control*, and who can deny himself nothing, he is likely to do as he pleases unless placed where he is absolutely controlled.

Unfortunately, this is to a degree the case with the majority, and the disease itself, as well as meddling interference and advice, favor it; even in an institution we have to exercise eternal vigilance to keep our patients determined and steadfast. We have to coax and to beg, to praise and commend, to scold and to threaten them into a course of lasting proper conduct.

On the other hand, if the profession send cases in the early stages, if they will explain to them that *now* every means are required and all proper efforts must be made to prevent the disease assuming serious proportions, if they will explain to their patients how important an ideal conduct even at a health resort will be, if they will tell them that there is no royal road, but one to be traveled with the greatest care and circumspection, that it is one beset with difficulties, only to be overcome by watching every minute detail and under the constant guidance of a competent, painstaking, honest physician, and recommend their patient to such a one—if, then, the patient is sent to one favorable climate or another, it will depend upon him, upon the compliance with advice, and a sufficiency of time given to a cure, whether the patient returns better or worse, improved or cured.

It is the stage of the disease reached, the proper conduct of the patient, the proper care and advice at the resort, and the time given, that determines the outcome of the case, and even the best physicians at health resorts must on that account leave it largely in the hands of the profession what their efforts shall accomplish.

The home physician, knowing his case and requirements,

needs no special instruction as to the *particular resort* to select; he can, after considering all the factors in a case, know pretty well what he can expect, and, *other things remaining equal*, any resort where the climatic conditions are favorable, as indicated in the earlier part of this paper, will give him practically the same results. Looking upon climate as a remedial agent, it can not be expected to furnish an exception to our experience with other remedies, and the results derived from any of them are influenced by the conditions and surroundings spoken of above.

THE WINYAH SANITARIUM, November 4, 1891.

## A DEVICE TO PREVENT MOUTH-BREATHING DURING SLEEP.

BY THOMAS R. FRENCH, M. D.,  
BROOKLYN.

WHEN, from any cause, the nasal passages are greatly diminished in size or occluded, breathing through the mouth is, of course, a necessity; but even after the cause has been removed the habit of mouth-breathing not infrequently persists. Again, this injurious habit is often practiced because of relaxation of the muscles of the lower jaw during sleep. The mouth may be closed on going to sleep, opened while sleeping, and when consciousness arrives is found closed again, so that many are ignorant of the fact that they ever breathe through the mouth. Adults who present symptoms of the practice of this habit during sleep will, as a rule, deny its existence, but if they are questioned closely they will usually admit that the mouth and throat are almost always dry in the morning, and that it may be several hours before those parts regain their normal condition.

For all cases in which the presence of the habit is known or suspected, and also to determine the existence of sufficient nasal capacity during sleep, it has been my custom, in the past few years, to direct the use of strips of a material known as "wash blonde" in such a way that, if the nasal passages are sufficiently free, the lower jaw will be held in place, and, as a consequence, nasal breathing enforced. With the kind assistance of Mr. S. V. W. Lee, recently under my professional care, this device has been much improved and is serving an excellent purpose.

The device consists of a piece of "wash blonde," a kind of "illusion," which is attached to straps of light webbing and adjusted to the head in the manner shown in the accompanying sketch.

The "wash blonde" is placed under the chin and the perpendicular straps buckled together at the top of the head.

In this way the needful support is given to the lower jaw. The perpendicular straps are held in position on the head by two back straps, which are looped on to them, and which are also regulated by a buckle. The buckle at the top of the head is padded to prevent uncomfortable pressure being made, and the whole appliance is so light and elastic that it is usually worn, after a trial or two, without the slightest discomfort.

The apparatus is made in two sizes, for adults and children, and is supplied by Messrs. F. Haslam & Co., 83 Pulaski Street, Brooklyn.

## FRACTURE OF THE RADIUS.

*NON-UNION; OPERATION; RECOVERY.*

By W. H. HODGMAN, M. D.,

SARATOGA, N. Y.

AFTER an interested perusal of the cases of non-union following fracture of the leg, reported by Dr. Fred. Jenner Hodges, of Chicago, in the *Journal* for October 10, 1891, I determined to operate, and, finally, to report the following case, not so much for the sake of reporting the operation itself as to illustrate what seems to me a somewhat unique cause for non-union:

On October 9, 1891, William Y., fifty-one years of age, a strong, well-developed, and healthy man, of excellent habits, was, while driving a team attached to a carriage, thrown out upon the ground and dragged some distance down a hill. The pole of the carriage had broken, plowed into the road, and overturned the vehicle. Just how the injuries were received, except that a wheel passed over the right ankle, he can not remember. To him the result of the accident was a broken right fibula in its lower third, a transverse and comminuted fracture of the lower end of the radius at about the junction of its middle and lower thirds, and a very oblique fracture of the same radius, the lower portion of which was about three inches above the transverse fracture. These, together with a number of cuts, scratches, and bruises on the face, limbs, and various other parts of the body, completed the casualties. The leg was put up in felt splints and fracture box until the swelling had subsided, when plaster was substituted. This was allowed to remain in place until six weeks after the injury was received, when, on removal, it was found to be united and apparently all right. The forearm, which was much swollen when first seen by me, was dressed with two straight, flat splints, somewhat wider than the arm. The outside splint reached from immediately below the olecranon process to a point midway between the wrist and the lower ends of the metacarpal bones. The anterior splint extended from the bend of the elbow to the wrist joint. The splints were each padded with two layers of Canton flannel, having their centers elevated by a narrow ridge made by several folds of the same material; all being held in place by strips of rubber plaster. The splints and forearm were retained in position in the usual manner by rubber plaster, roller bandage, and sling. After four or five days, the swelling having considerably subsided, the arm was carefully examined and the splints reapplied. In a few days more, the swelling having entirely gone out, the splints were firmly applied and not again removed until four weeks from the date of the injury. After the first dressing the patient suffered no pain or inconvenience whatever. At this time it was found that no union had taken place at either end of the fracture. I rubbed the ends together as well as I could, reapplied the splints, and left them on for

nine days. At the expiration of this time it was quite evident that some union had taken place in the upper or oblique fracture, though absolutely none in the lower or transverse fracture.

Acting now on the advice of one of the best surgeons in northern New York, I decided to operate without further delay. Preparations were made for a thoroughly aseptic operation, including sterilization by boiling of all the water to be used, and sterilization by steam of all instruments and sponges.

An incision was made directly over the center of the radius on its dorsal aspect, commencing about an inch below the lower fracture and extending about an inch and a half above. On getting the bone well exposed, it was found that the ends were not in perfect apposition. The lower end of the radius had a piece broken almost squarely out on its ulnar side that dipped into the bone nearly half its width, and within this notch the lower end of the upper piece was resting, thus creating a condition of things that, in this muscular arm, did not show any deformity to my eye or sense of touch. The small piece that had been broken out had disappeared. After separating and freshening the ends, it was found impossible to bring them together properly on account of the overlapping. The incision was now extended up the forearm so as to completely expose the upper fracture, when the cause of the overlapping below became apparent. The upper fracture, which was very oblique, had allowed the loose piece to slip, or be drawn directly downward by muscular action, until its lower end rested in the notch in the upper portion of the lower end of the radius, thus creating another malposition of the fragments that could not be detected until dissection had laid it bare. No nerve or fragment of muscle was found interposed between the ends, and if, as is now taught, the course or relation of the nutrient artery is not to be considered, then it must have been this slight slipping downward and the inability of the splint to hold the pieces firmly together that in this case caused, in one instance, delayed union, in the other non-union. For, as before stated, there was absolutely nothing perceptible in the patient's general condition to cause a suspicion in that line. The much-despised chain saw was now brought into use, and it did its work quickly, smoothly, and well. With it a small piece was sawed from each end, the bone drilled, and, with a doubled piece of No. 26 silver wire, brought together firmly and accurately. The oblique fracture in which union had commenced was, of course, not disturbed. The muscles and deeper tissues were stitched with catgut, the skin and areolar tissue with silk. No drainage. The external wound was seven inches in length. Iodoform, iodoform and sublimate gauze, a plain plaster splint from wrist to elbow, with sling, completed the dressing. The patient sat up the next day and had at no time any elevation of temperature or pulse, or sensation of pain in the wound. Thirty-eight days after the operation the plaster splint and other dressings were removed. The bone and soft parts had firmly and perfectly united. The muscles are now getting loose and free, with every prospect of a strong and perfect arm. To Dr. Inlay, Dr. Thompson, Dr. Humphrey, and Mr. Gates, student, I am much indebted for conscientious and valuable assistance.

**The Jefferson Medical College, of Philadelphia.**—The board of trustees, at a meeting held on April 7th, instituted a chair of clinical gynecology, with a seat in the faculty, and elected to the new chair Dr. E. E. Montgomery, who has been for a number of years professor of gynecology in the Medico-surgical College. They also elected the following clinical professors: Dr. F. X. Dercum, professor of nervous diseases; Dr. E. E. Graham, professor of children's diseases; Dr. H. Augustus Wilson, professor of orthopedic surgery; Dr. H. W. Stelwagon, professor of dermatology; and Dr. W. M. L. Coplin, adjunct professor of hygiene.

NEW YORK, SATURDAY, APRIL 16, 1892.

FATAL MALARIAL POISONING.

In the *Johns Hopkins Hospital Bulletin* for December, Dr. Osler is reported, in the proceedings of the hospital society, as giving an account of two fatal cases of paludal poisoning. Malarial poisoning so seldom causes death in the latitude of Baltimore that these carefully studied cases are full of interest. One of them illustrated the algid type and the diagnostic value of examination of the blood. In the other case the diagnosis was befogged by the history of an insolation and by some pulmonary symptoms, so that before the patient's death the case was set down as one of low anomalous pneumonia. The blood was examined superficially and no malarial organisms were found.

The first, or algid, case was that of a sailor, thirty-four years old, recently from Savannah, without a history of chill or fever, but with persistent vomiting and great prostration. His temperature on admission was 101° F., and his pulse 104. The blood was examined at once, and, as was expected, Laveran's organisms were found in large numbers. Six or eight intra-corpuseular forms could be seen in the field of the one-twelfth immersion, the majority of which were without pigmentation. They underwent rapid changes of outline. An unusual proportion of the leucocytes showed pigment granules. Half-drachm doses of quinine were given every six hours; when vomiting was excessive the quinine was given subcutaneously. The treatment seemed to have the effect of diminishing the number of plasmodial corpuscles, but the patient died after being six days in the hospital.

The second, or supposed pneumonic, case, was that of a man, apparently in vigorous health, who had been employed as a berry-picker in July. He died at the end of a fortnight. The necropsy showed no pneumonia, although there were pulmonary congestion and œdema. The post-mortem diagnosis was that of malarial fever with malarial parasites in the blood and in the spleen. The microscopical examination was made by Dr. Welch, who noted that blood from the finger showed in small numbers malarial organisms—namely, spots of the shape and size of the red blood-corpuseles with pigmented plasmodia; free round pigment corpuscles, varying in size from that of blood plates to twice that size; and pigmented crescents, the pigment being in a ring in the middle. He found in one specimen of splenic pulp two free and active flagella. A few pigmented corpuscles were found in the capillaries of the brain.

The case last reported was the earlier of the two by a year or two; and, while Dr. Osler does not so state, he leaves the reader to infer that his experience with that case was a means to the almost immediate recognition of the malarial poisoning in the case of the young sailor.

MEDICAL MISSIONARY WORK IN EAST CENTRAL AFRICA.

From a publication issued by the Universities' Mission to Central Africa we learn something concerning the line of work performed in connection with the hospital at Zanzibar. That institution, manned and supported largely by men of the universities of Oxford and Cambridge, is little more than a dispensary at present, with one small ward near by. The cornerstone for a large hospital, situated close to the old Slave Market, in the capital of Zanzibar, was laid on May 12, 1891. Already the walls are rising—rapidly for that part of the world—and another year will see there a regularly equipped hospital, with trained nurses from England. The cost will not be less than \$10,000, providing two wards for the natives and some private accommodations for Europeans who fall ill with the tropical fever. These latter require prompt and special attention; many lives are lost by delay in seeking treatment. The location of the hospital is especially suitable for such relief, since its site is regarded as the most salubrious part of the town.

The paragraph relating to the small-pox epidemic of 1887 will be interesting reading to all who have not lost faith in Jenner's great discovery. The ravages of small-pox among the native Africans, when it is not tempered by vaccination, are extreme and almost beyond the range of descriptive language.

A LARGE FOREIGN BODY TOLERATED IN THE  
CONJUNCTIVAL SAC.

Dr. F. M. CHESLUM, of Baltimore, reports, in the *Maryland Medical Journal* for March 26th, a case illustrative of the remarkable tolerance of the conjunctiva of a large foreign body, provided that the substance gains entrance to the retrotarsal fold of the upper lid. His patient, a little girl of nine years, gave a history of having been struck on the right eye about four months before coming under his charge. The nature of the blow was not understood, and the results were apparently transient and not marked by painful symptoms. A mild astringent lotion was all that was used to allay a certain amount of conjunctival irritation. But a prominence of the upper lid was noticed, and a little later a dark object made its appearance at the inner canthus of the eye. On examination, there came into view a piece of round twig seven eighths of an inch long by an eighth of an inch in diameter. This had been under the lid nearly four months, in about the same position, until the child probably, while rubbing her eye, caused the piece of wood to appear at the canthus. Before this change of position, mere eversion of the lid would not have exposed the foreign body, since its situation was in the cul-de-sac, behind the tarsal cartilage. The length of time this visitor was detained was as remarkable as the slight degree of annoyance caused by it. The palpebral conjunctiva showed a certain amount of congestion, but the appearance of the eyeball was normal.

Foreign bodies, such as bits of wood, seeds of considerable size, and beads of different kinds, when they become lodged behind the upper tarsal fold, sometimes escape the attention of the

general practitioner, and the conjunctival irritation is treated as a conjunctivitis from cold or external violence; but ordinarily their presence is indicated by a painless swelling or elevation looking externally very much like a tarsal tumor. On palpation, however, the fingers recognize that there is a freedom of motion, as of a foreign body under the integument, that does not belong to a tumor of the lids.

MINOR PARAGRAPHS.

CHLOROFORM IN THE TREATMENT OF TYPHOID FEVER.

ACCORDING to the *Lancet*, Dr. P. Werner has treated 130 cases of typhoid fever with a one-per-cent. solution of chloroform, the employment of which was suggested by Behring's observations of the germicidal action of chloroform upon the bacillus. Werner gave a tablespoonful of the solution every hour or every two hours during the height of the disease and for some days after the temperature became normal. In all cases in which this treatment was adopted before the tenth day great improvement was manifested; the tongue did not become brown, diarrhoea and tympanites gradually disappeared, there was no tendency to bed sores, and relapse was very rare. His observations agreed with those of Steppe, who used the drug in 1890 in this disease. Possibly we may have in this a desirable substitute for the so-called Brand treatment, of which Osler says in his recent work: "To transfer a patient from a warm bed to a tub at 70° F., and to keep him there twenty minutes or longer in spite of his piteous entreaties, does seem harsh treatment, and the subsequent shivering and blueness look distressing. A majority of our patients complain of it bitterly, and in private practice it is scarcely feasible."

CATHETERISM OF THE BILIARY PASSAGES.

IN the February number of the *Revue de chirurgie* Dr. Terrier and Dr. Dally conclude an exhaustive article on catheterism of the biliary ducts in conjunction with cholecystotomy or in the treatment of the case after the performance of that operation. They think that this procedure is easier in pathological cases, especially those in which the passages are dilated in consequence of retention of bile, than it would be in experimental trials on the cadaver. In many cases it would be found difficult on account of curvatures of the cystic duct, or of the persistence of the valves, or of the cystic duct opening on the lateral wall of the gall-bladder. In some cases the difficulties will be insurmountable, while in others the exploration will be found quite easy. To formulate rules for this sort of catheterism is impossible; one can only be guided by one's anatomical knowledge. Forced catheterism, even with the finger placed under the liver in the abdomen, seems to be dangerous under all circumstances. Our information is as yet not sufficient to enable us to appreciate the value of *cathétérisme à demeure*. The instruments employed should always be sterilized.

THE SURGEON-GENERAL OF THE NAVY.

THE President has wisely settled the question of the succession to Surgeon-General Brown by re-appointing him. Dr. Brown had just completed his four years' tenure of office, and only about thirteen months remain before the time of his retirement will arrive. It is understood that nearly all the other candidates for the appointment made their applications with the proviso that they were not in the field if Dr. Brown's re-appointment was to be considered. Surgeon John C. Boyd will be appointed assistant to Dr. Brown, to take the place of Medi-

cal Inspector William K. Van Reyepen, who will join the San Francisco in a few weeks as fleet surgeon of the Pacific station.

A PRESCRIPTION FOR YOUNG PHYSICIANS.

ACCORDING to the *British Medical Journal*, a distinguished Vienna professor gives the following prescription to all young physicians who call to take leave of him before embarking on their professional career: *R* Veritatis, humanitatis, fidelitatis, aā infinitum. *Mi*sc. Ft. elixir vitæ. *Signa*: To be used constantly throughout life. It is easy, perhaps, for most men to start with a good stock of this spiritual elixir, but the difficulty is to find an apothecary who can dispense the prescription when the supply has run out.

ETHER-DRINKING IN RUSSIA.

THIS vice, says the *British Medical Journal*, has spread so rapidly in Russia that the Government has prohibited the free sale of ether and certain of its compounds. Such legislation has proved to be efficacious in diminishing the vice in Ireland.

ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the week ending April 12, 1892:

DISEASES.	Cases.	Deaths.
Typhus Fever.....	3	1
Typhoid fever.....	11	3
Scarlet fever.....	258	23
Cerebro-spinal meningitis.....	6	3
Measles.....	460	25
Diphtheria.....	137	24
Small-pox.....	26	..

**The Circle of Willis**, we learn by a letter from Dr. Frank A. McGuire, is a society that has recently been organized in New York for the purpose of diffusing social ideas among the medical profession, to the exclusion of "shop." The society has twenty members, and is receiving accessions monthly. It will be seen that it is analogous to the Austin Flint Society, of Baltimore, mentioned by us recently.

**Gowers on the Nervous System.**—We learn that a German edition of the second revision has just been published in Bonn, also that an Italian translation is nearly ready.

**The Hospital Graduates' Club.**—The fifty-ninth stated meeting will be held at the "Arena," No. 41 West Thirty-first Street, on Thursday evening, the 28th inst. Dr. Norris is announced to read a paper on The Internal Administration of Ozone in the Treatment of Phthisis.

**The Middleton Goldsmith Lecture.**—The trustees of the Middleton Goldsmith fund have invited Dr. Francis P. Kinnicutt to deliver the lecture this year, on Friday, May 6th.

**Change of Address.**—Dr. Charles N. Cox, to No. 168 Halsey Street, Brooklyn.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 27 to April 9, 1892:*

- WOOD, MARSHALL W., Captain and Assistant Surgeon. The leave of absence granted is extended one month.
- MACAULEY, C. N. B., Captain and Assistant Surgeon, will report for temporary duty at U. S. Military Academy, West Point, N. Y., during the absence of Captain HENRY S. KILBOURNE, Assistant Surgeon, as member of the Army Medical Board, New York city, N. Y., and on return of that officer will rejoin his proper station.
- MERIWETHER, FRANK T., First Lieutenant and Assistant Surgeon. Ordered for temporary duty at Madison Barracks, New York, during

the absence of Captain HENRY S. TURRILL, Assistant Surgeon, as member of Army Medical Board, New York city, and on return of that officer will rejoin station.

HOFF, JOHN VAN R., Major and Surgeon. Ordered to St. Louis, Mo., to represent the Medical Department of the Army at the meeting of the Association of Surgeons of the National Guard, to be held in that city April 19 to 21, 1892.

WINTER, FRANCIS A., First Lieutenant and Assistant Surgeon (recently appointed), will proceed from St. Louis, Mo., to Jefferson Barracks, Mo., and report to the commanding officer of that station for duty.

The suspension of the operation of Par. 2, S. O. 13, January 16th, A. G. O., relating to APPEL, AARON H., Captain, and CABELL, JULIAN M., First Lieutenant and Assistant Surgeon, is removed.

GARDNER, EDWIN F., Captain and Assistant Surgeon, is granted leave of absence for one month on surgeon's certificate of disability.

SUTER, WILLIAM N., First Lieutenant and Assistant Surgeon. Resignation has been accepted by the President, to take effect July 28, 1892.

IRELAND, MERRITTE W., First Lieutenant and Assistant Surgeon. Ordered to Fort Yates, North Dakota, for temporary duty during the absence of Captain Alonzo R. Chapin, Assistant Surgeon, on sick leave.

HARTSUFF, ALBERT, Major and Surgeon. Granted leave of absence for six months, to take effect on or about July 10, 1892, with permission to go beyond the sea and to apply for an extension of two months.

BRADLEY, ALFRED E., First Lieutenant and Assistant Surgeon. Ordered to Columbus Barracks, Ohio, for temporary duty at that station during the illness of Captain Augustus A. De Soffre, Assistant Surgeon.

PURVIANCE, WILLIAM E., First Lieutenant and Assistant Surgeon (recently appointed), will proceed from Rossville, Ill., to Fort Riley, Kansas, and report for duty at that station.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the two weeks ending April 9, 1892:*

LEWIS, D. O., Surgeon. Detached from the Naval Hospital, Washington, and ordered to the Naval Hospital, Mare Island, California.

BERRYHILL, T. H., Passed Assistant Surgeon. Detached from the U. S. Steamer Pensacola and ordered to the U. S. Steamer Ranger.

BARNUM, MERRILL W., commissioned an Assistant Surgeon in the Navy from March 15, 1892.

FARWELL, W. G., Surgeon. Granted leave of absence for six months, with permission to leave the United States.

WOODS, GEORGE W., Medical Inspector. Detached from the U. S. Steamer Pensacola, and ordered to the Hospital at Mare Island, California.

BATES, N. L., Medical Director. Detached from the Naval Hospital, Mare Island, California, and ordered home.

BROWS, J. MILLS. Reappointed Chief of Bureau and Surgeon-General.

BOYD, J. C. Detailed as Assistant to the Bureau of Medicine and Surgery.

BARNUM, M. W., Assistant Surgeon. Ordered to the Naval Hospital, Washington, D. C.

SMITH, HOWARD, Surgeon. Granted leave of absence for six months, with permission to leave the United States.

McCULLOUGH, CHAMP CARTER. Commissioned an Assistant Surgeon.

#### Society Meetings for the Coming Week:

MONDAY, *April 18th*: New York County Medical Association; New York Academy of Medicine (Section in Ophthalmology and Otology); Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, *April 19th*: Association of Military Surgeons of the National Guard of the United States (first day—St. Louis); Medical Society of the State of California (first day—San Francisco); New York Academy of Medicine (Section in General Medicine); New York Obstetrical Society (private); Medical Societies of the Counties of Kings and Westchester, N. Y.; Ogdensburg, N. Y., Medical Association; Passaic, N. J., County Medical Society (annual); Baltimore Academy of Medicine.

WEDNESDAY, *April 20th*: Association of Military Surgeons of the National Guard of the United States (second day); Medical Association of Montana (first day—Butte); Mississippi State Medical Association (first day—Natchez); Medical Society of the State of California (second day); Medical Association of Georgia (first day—Columbus); New York Academy of Medicine (Section in Public Health and Hygiene); Harlem Medical Association of the City of New York; Northwestern Medical and Surgical Society of New York (private); Medico-legal Society (New York); Philadelphia County Medical Society; Windham, Conn., County Medical Society (annual—Plainfield); Middlesex, Mass., South District Medical Society (annual—Waltham).

THURSDAY, *April 21st*: Association of Military Surgeons of the National Guard of the United States (third day); Mississippi State Medical Association (second day); Medical Association of Montana (second day); Medical Society of the State of California (third day); Medical Association of Georgia (second day); New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private); Tolland, Conn., County Medical Society (annual).

FRIDAY, *April 22d*: Mississippi State Medical Association (third day); Medical Association of Georgia (third day); Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

SATURDAY, *April 23d*: New York Medical and Surgical Society (private); Worcester, Mass., North District Medical Society (annual—Fitchburg).

## Obituaries.

EDWARD WIGHT CLARKE, M. D., OF ENGLEWOOD, N. J.

THE death of this very promising young practitioner took place on Monday, the 11th inst., after an illness of less than a week's duration. Dr. Clarke was born in Manchester, New Hampshire, on the 20th of October, 1862. In 1883 he received the degree of bachelor of arts from Columbia College, after which he took a special course in the same institution, and took the degree of master of arts in 1884. In 1887 he received his medical degree from the College of Physicians and Surgeons, taking the third Harsen prize. He then served the full term on the house staff of one of the surgical divisions of the New York Hospital. During his service in the hospital he showed much originality in treatment. Among other things, he devised a method of treating fracture of the patella by means of a subcutaneous suture. He was one of the founders of the Association of the Alumni of the New York Hospital. Since leaving that institution he had practiced in Englewood. The cause of his death was septicæmia occurring in the course of scarlet fever. He leaves a widow, a daughter of Dr. Banks, of Englewood, and two children.

## Letters to the Editor.

AN OPENING FOR MEDICAL LADIES IN INDIA.

111 NORTH EIGHTH AVENUE, MOUNT VERNON, N. Y., *April 2, 1892.*

*To the Editor of the New York Medical Journal:*

SIR: You had the kindness to insert in one of the January numbers of your journal a notice of the need of a fully quali-

fied physician to take the supervision of a medical mission in Ceylon. We received many responses to that appeal, and are happy to say that a suitable candidate has been found and is now under appointment for that work.

We have been requested to make another appeal for two fully qualified lady doctors for medical work in India, under the Zenana Bible and Medical Missionary Society of London, whose honorary missionaries we are.

There are 139,000,000 women in India, including 21,000,000 widows, 79,000 being children under nine years of age. *Thousands of women and girls die annually whose lives might have been saved by proper medical assistance.* There is only one missionary for every 250,000 of the population.

The Zenana Bible and Medical Mission, which was founded in 1852, is unsectarian and works in co-operation with different missionary societies in India. Its object is to give medical relief to the women of India and make known to them the gospel of Christ. The agencies it employs are as follows: Fully qualified lady doctors, lady missionaries, native Christian assistants, Bible women, day schools for girls, training schools, village missions, also hospitals and dispensaries, the attendances last year at which were over 22,000.

The society's work has nearly trebled during the past ten years. Appeals for more missionaries are constantly received, to which the committee are ready to respond as soon as suitable candidates can be found. The age of the medical ladies who apply should not exceed thirty years. The salary allowed is about \$650 to \$750 per annum, with extras, such as outfit, passage, rent of house, traveling, etc. The ladies must be earnest Christians, thoroughly unsectarian in their sympathies, and ready and willing to work with all evangelical churches and with all workers who love our Lord Jesus Christ in sincerity and truth. It is the custom of this society to place two medical ladies at a station, furnishing them with a hospital, dispensaries, medicines, and a suitable staff of trained native assistants. Its medical missionaries thus enjoy advantages which are not always afforded to the medical missionaries of other societies. We shall be glad to give further information about the work of this society to any one really contemplating offering herself for this work. We are also desirous of having an interview with such, and shall be glad to see any one at the address given above at any time during the last week in April or the first week in May. Any one desiring to apply should do so forthwith, as we wish to secure these candidates before we return to England, which we shall probably do in May. Sincerely,

MARY AND MARGARET W. LEITCH,  
*for seven years missionaries in Ceylon.*

## Proceedings of Societies.

### SOCIETY OF THE ALUMNI OF BELLEVUE HOSPITAL.

*Meeting of October 7, 1891.*

The President, Dr. EGBERT LE FEVRE, in the Chair.

#### An Extreme Case of Congenital Lateral Curvature.—

Dr. R. H. SAYRE presented a remarkable example of congenital lateral curvature of the spine in a girl fourteen years of age. At the time of her birth it had been noticed that she had a short, catching respiration, and a few hours later a careful examination had showed that there was a marked lateral curvature of the spine with rotation of the ribs on the left side. At

the age of six years she had had pneumonia, followed by an abscess, which had opened through the right thoracic wall. From its coming so closely upon the attack of pneumonia, it had been probable that this abscess had communicated with the pleura, and although it had undoubtedly aggravated the condition of the spine, it could not be said to have originated it, as this condition had long antedated the pneumonia. The child had received no systematic treatment up to the time of her first coming to the speaker, four days ago. Examination at that time had showed a large V-shaped gap in the ribs over the liver, which was probably not due to the absence of any ribs, but to a fracture of the costal cartilages *in utero*. This condition probably accounted for the extraordinary amount of malformation, which was greater, the speaker thought, than that of any congenital case on record. Her height was found to be four feet six inches and three quarters. During the past four days she had been stretched daily by means of the well-known Sayre suspension apparatus, and had gained each day about an eighth of an inch in height. He desired to call particular attention to this fact, for, while it was easy to understand how such suspension might cause a very temporary increase in stature, it was very surprising that this gain in height could be retained. A good deal of doubt had been expressed by various writers as to the possibility of increasing the height in this way, but he would remind his hearers of one or two similar cases which he had already presented to the society, in which such a result had been actually obtained, and where the measurements had been taken by others as well as by himself.

Dr. L. W. HUBBARD had seen in his service at the New York Orthopædic Dispensary two or three cases of quite marked lateral curvature with rotation and bulging of the ribs, in very young children, and the parents of these children had stated that the deformity had been first noticed either at the birth, or within a few days thereafter. The case just presented seemed to him to have originated from a congenital absence of the ribs, or else from a separation of the ribs at the sternal ends, thereby allowing the pressure of the uterine walls to crowd together the ribs, and so give rise to the deformity. Undoubtedly this had been stealthily increasing as a result of a lack of support on that side. Suspension and proper support would undoubtedly increase the height, but he hardly thought it would exert any very appreciable effect upon the deformity itself.

Dr. SAYRE said that there had already been some reduction of the deformity, as was shown by the fact that garments which could be buttoned around the chest a few days ago could not be readily so fastened. He thought, therefore, he was justified in looking for a considerable improvement in the deformity.

Dr. SAYRE also presented a young girl having some disability of one hand, the exact nature of which he did not fully understand. He presented her with a view of eliciting suggestions as to the aetiology and treatment. A year or so ago, she said she had been cut across the right wrist by a long, straight knife, and so severe had been the injury that the bones had been plainly visible in the wound. An effort had been made to unite the extensor tendons, as well as the lips of the wound, by sutures. She stated that about four months later it had become necessary to break up some adhesions, and that after this had been done the motion of the hand had been better. Electricity and massage had been employed for some time and had been of some service. She had been treated for a while at the orthopædic dispensary, but had become discouraged and had abandoned treatment. He had seen her for the first time that afternoon. The hand became blue and cold on slight exposure, and a hasty examination had showed a total paralysis of the digital flexors and extensors, for they were not under the control of the will,

and did not give any reaction with a strong faradaic current. A galvanic battery had not been at hand at the time this first examination was made. The interossei and the opponens muscles of the middle finger and thumb had appeared to be normal, as were also the flexors and extensors of the carpus. There had also been great rigidity of the knuckles, which projected into the palm just as they did in certain nervous disorders. The situation of the wound had not been such as to explain the condition by supposing that there had been an injury of a nerve, and, as the knife was said not to be curved, it could not be supposed that the flexor tendons in the palm had been severed, and that the attending surgeon had overlooked them when suturing the other tendons.

Dr. HUBBARD said that he had seen the case at the orthopaedic dispensary when the patient had first applied for treatment, and she had then mentioned certain points in the history which had not been given in the foregoing recital. The arm had been kept on a splint for a number of months after the injury, and then, after breaking up the adhesions, it had been again confined on a splint for about seven months. There had been considerable inflammatory reaction and some suppuration. He had felt quite sure that there had been some muscular control, and that at the time he had seen her the muscles had reacted to electricity. The action of the muscles above the carpus had been shown when the patient's fingers had been flexed. At first the fingers had been quite stiff and the circulation very poor, but under electricity and massage there had been a very noticeable improvement up to a certain point, and then it had been so slow that the patient ceased to attend regularly at the dispensary. He thought that the condition present was entirely due to the crippling of the tendons by inflammatory adhesions.

Dr. IRVING S. HAYNES fully concurred in this view.

Dr. SAYRE replied that he did not doubt that much of the disability was due to the crippling of the tendons by adhesions, but this did not explain the reason for the flexors not acting upon the terminal joints of the fingers, and what little resistance there was to the flexion of these joints seemed to be due to the action of the interossei and lumbricals rather than to adhesions.

**Vicious Union following Pott's Fracture; Operative Treatment; Exhibition of a Case.**—Dr. IRVING S. HAYNES read a paper on this subject. (See page 423.)

Dr. L. W. HORTCHKISS had seen during the past winter a case of Pott's fracture with bad union, treated in Bellevue Hospital according to the plan described in the paper, a simple osteotomy being done through the shaft of the fibula above the external malleolus. The result had been all that could be desired. He recalled seeing Dr. McBurney operate about six years ago in Bellevue Hospital upon a case in which both bones had been fractured. The case had been treated for some time after the injury by means of two lateral wooden splints without any attention being paid to the flexion of the foot. As a result of this the foot had become extended and abducted and the patient had walked on the ball of the foot while the ankle joint had been stiff and painful. The patient had accordingly sought relief in the hospital and the deformity had been perfectly reduced by an osteotomy on both bones. There were not in the hospital plaster casts representing the condition present before and after the operation.

Dr. HUBBARD had seen a number of these cases where, years after the operation, the disability had been extreme. Considerable relief had been afforded by a mechanical support consisting of a stout ankle-piece passing underneath the shoe, with a large pad to support the inside of the foot, and the usual bars passing up on either side of the leg. In the patient just presented there was evidently a shortening of the tendo Achillis,

and when the patient stood with the feet flat on the floor there was a tendency to outward deviation. He was of the opinion that a gradual shortening of the tendon would take place, and would ultimately lead to a deformity similar to, but not so great as, the original one. This might be prevented by flexing the ankle by a suitable traction apparatus. If this were not done, after a number of years the internal ligament would probably yield, and there would not only be deformity and disability of the foot, but the patient would in all probability suffer, as he had seen others do, from cramps about the ankle and tarsus, and, later on, even running up the leg.

Dr. SAYRE could not see the reason for the tendon contracting in the manner described, as the mere fact of the patient walking and attending to his daily occupation meant that the tendon would be frequently stretched, and hence the condition of the foot should improve instead of developing into an equinus. It would no doubt be wise to stretch the gastrocnemius muscle, and break up some of the adhesions still remaining in front of the ankle. He had seen many of these cases which had been originally treated as a simple sprain by rest in bed and the use of fomentations, and the large number of such cases would seem to indicate that the medical profession at large was inclined to overlook slight Pott's fracture. This was especially true where such fractures occurred in fat old ladies, whose abundant adipose tissue made it difficult to detect the exact nature of the injury to the bones.

Dr. HUBBARD explained that he did not mean that the deformity would result in an equinus, but that where there was imperfect flexion of the foot, the continued use of it in this position would, after many years, result in an equino-valgus and a crowding together of the small bones of the foot. Such cases occurred without any previous injury.

Dr. SAYRE said that he was well aware that a short tendo Achillis often gave rise to valgus and a breaking down of the arch of the foot, for Nature intended that the ankle joint should be bent to an angle of about 120° with the tibia, and when this degree of flexion could not be obtained the person must move forward by bending the medio-tarsal joint. Under these circumstances he was very apt to stretch the plantar fascia and break down the arch of the foot, thus giving rise to a valgus. He did not believe, however, that the tendo Achillis kept on shortening all this time.

Dr. HAYNES said that he only desired to emphasize one point touched upon in the discussion—viz. the importance of treating a sprain as if it were a fracture. The reason for this was obvious, as one phase of a Pott's fracture was a rupture of the internal lateral ligament, and if union occurred with this ligament elongated, the state of the ankle would be worse than if the original injury had been a fracture. Hence every sprain of the ankle should be treated with a plaster-of-Paris dressing; it would certainly get well more quickly than by any other method.

---

## Book Notices.

*Hospitals and Asylums of the World; their Origin, History, Construction, Administration, Management, Legislation, etc.* By HENRY C. BURDETT, formerly Secretary and General Superintendent of the Queen's Hospital, Birmingham, etc. London: J. & A. Churchill, 1891. Vols. I and II. Pp. xvi-701; x-348.

To those interested in hospital construction the name of this author is well and favorably known, and the scope of the pres-

ent work will be appreciated by everybody when it is learned that the author has been engaged for the past twelve years in preparing and completing the material for publication—material that represents the experience of twenty-five years as a hospital official in various capacities and as a visitor to the chief institutions in most European countries, to those in several of the British colonies, and to those in the United States. It has been his aim to enable everybody interested to gain a more general and accurate knowledge of a work that must tend materially to “diminish suffering and to increase the comfort of those members of the community who are least able, or wholly unable, to make provision for themselves”; and this may, in part, be accomplished by intercommunication and co-operation among all administrative officers of asylums and hospitals throughout the world.

The first volume is devoted to a history of asylums and of their administration, and begins with the early history of insanity. Attention is called to the fact that Aretæus, of Cappadocia, and Paulus Ægineta, almost six hundred years later, insisted upon the rational treatment of violent maniacs and the employment of only the kindest and simplest restraint. But their teaching went unheeded or was forgotten in what Maxime du Camp called the period of “engulfment,” and less than a century ago Pinel succeeded in awakening public and professional conscience to a realization of public responsibility for the insane. The author finds that at Metz in the year 1100, and at Dantzic in 1320, there were asylums for the insane, thus disproving Desmaison’s contention that the establishment of the Valencia asylum marked an epoch in the treatment of these unfortunates.

From a consideration of the period of brutal suppression, ill-treatment, and cruelty to the insane, and of the early history of lunacy and asylum treatment in the British colonies and abroad, the author passes to the present condition of lunatic asylums, and gives an encyclopædic *résumé* of those institutions in various parts of the world.

As Americans our pride may be touched by such a passage as this: “Were it not for the lavish expenditure in sanitary matters and the introduction of all the latest scientific appliances for minimizing labor and risk, it would almost appear that lunatics in America were still regarded as a class to be confined first, and perhaps cured afterward, rather than as unfortunate beings for whose curative treatment these enormous buildings have been designed.” And: “So common, indeed, is it [overcrowding] that it may almost be said to be the rule, whereas in other parts of the world it is certainly the exception.” The justification of the former criticism may be found, in this State at least, in the Annual Report of the State Commission in Lunacy for 1890, and our acquaintance with other communities permits us to say that New York is not alone in the matter. Mr. Burdett is aware that the responsibility for this condition of affairs does not rest entirely upon the medical profession; and if more intelligence and less political jobbery were infused into the expenditure of the appropriations for the construction of insane asylums, the overcrowding at least might often be obviated, and it would be impossible to say, as has been said of the St. Louis Insane Asylum, that the money expended in the general construction of the institution would, if placed at interest, pay for the board and lodging of all the inmates at the best hotel in the city.

Regarding his criticism on the prevalent use of methods of restraint in most of our institutions, we must cry *peccavi*, and await the day when appropriations will be sufficiently generous to enable asylums to have that quota of skilled attendants that will enable them to dispense with what is yet often necessary in order to prevent the patients from harming themselves or others. This want, we believe, is oftener the *font et origo* of

the restraint employed than any lack of sympathy, intelligence, or progressiveness on the part of our superintendents of asylums.

The generous commendation the author bestows on whatever is commendable in American institutions shows that his criticisms are made in a spirit of fairness and not from a captiousness that we are often accustomed to from our English brothers.

The second volume treats of asylum construction, with plans and a bibliography. It would not be possible to do it justice in the space of a review, but we would commend it for careful perusal to all persons and boards interested in this subject.

*Transactions of the American Association of Obstetricians and Gynecologists.* Vol. IV, for the year 1891. Philadelphia: William J. Dornan.

This volume is quite abreast of those that have preceded it in scientific interest and value. To say that this association is composed largely of progressive men is only to state a well-known fact. They are to be congratulated upon the excellent character of the work that they are doing year by year and on the success they are having in presenting subjects for discussion that are of vital interest to gynecologists everywhere.

*Abdominal Surgery.* By J. GREIG SMITH, M. A., F. R. S. E., Surgeon to the Bristol Royal Infirmary; Lecturer on Surgery, Bristol Medical School; Late Examiner in Surgery, University of Aberdeen; Fellow of the Royal Medical and Chirurgical Society of London; Honorary Fellow of the American Society of Obstetricians and Gynecologists, etc. Fourth edition. Philadelphia: P. Blakiston, Son, & Co., 1891.

The fact that a fourth edition of this work has been called for within four years of the date of its first publication must be gratifying to the author. More than that, it is an evidence that the work is one of no ordinary value. Such a work was imperatively demanded by the marvelous extension of abdominal surgery within the past decade, and it is difficult to see how the demand could have been better satisfied. It is but just to say however, that there are some marks of haste in the preparation of this latest edition which might have been obviated had the requirements for its appearance been less urgent.

We have been unable to discover any reference to the use and value of the Trendelenburg posture, which is now recognized as one of the most valuable adjuncts in the performance of abdominal operations. On page 216 Leopold is said to have lost four out of eighty patients after vaginal hysterectomy, and, a little further on, “Sänger, Leopold, Olshausen, and a few others are said to have had results nearly as brilliant.”

On page 220 we observe that the author, in classifying cancer of the uterus, clings to the old division of scirrhus and encephaloid, which may well become obsolete. Why not say *hard* and *soft* cancer where the distinction is purely a clinical one? The use of clamps in preference to ligatures in vaginal hysterectomy is still advocated (p. 233), though it is admitted that there are disadvantages with the former and advantages with the latter. We are quite in accord with the positive statement of opinion, based upon experience, that in vaginal hysterectomy it is perfectly proper to leave the vaginal and peritoneal wounds open. Of course there are exceptions in which such a plan would not be the most desirable.

Upon the subject of ectopic gestation Tait’s record is quoted only to 1887. It must not be forgotten that much of the most valuable work in this field by Tait, Price, and others has been done since that date, and this oversight should not have hap-

pened in dealing with a matter of so great importance. Another oversight occurs in connection with the chapter upon appendicitis. It is true that McBurney's name is mentioned in connection with the disease, but it was deserving of far more extended notice, in view of the great value of the work that has been done by that distinguished surgeon in this field. We doubt not that proper appreciation will be extended in a subsequent edition, for there is no lack of fairness in the entire volume wherever it is apparent that good work has come to the author's notice.

There is no difficulty in recognizing the fact that the author is a man of positive convictions, and, while opinions are not advanced with unbecoming dogmatism, he has no hesitation in offering guiding statements, and we believe that, in the main, they will be found safe and trustworthy.

#### BOOKS, ETC., RECEIVED.

Bacteriological Diagnosis: Tabular Aids for Use in Practical Work. By James Eisenberg, Ph. D., M. D., Vienna. Translated and augmented, with the Permission of the Author, from the Second German Edition, by Norval H. Pierce, M. D., Surgeon to the Out-door Department of Michael Reese Hospital, Chicago. Philadelphia and London: F. A. Davis Co., 1892. Pp. xiv-3 to 184. [Price, \$1.50.]

Outlines of Zoology. By J. Arthur Thomson, M. A., F. R. S. E., Lecturer on Zoology in the School of Medicine, Edinburgh, etc. With Thirty-two Full-page Illustrations. New York: D. Appleton & Co., 1892. Pp. xvi-341.

Transactions of the New York State Medical Association for the Year 1891. Volume VIII. Edited for the Association by E. D. Ferguson, M. D.

Lectures on Tumors from a Clinical Standpoint. By John B. Hamilton, M. D., LL. D., Professor of Surgery and Clinical Surgery, Rush Medical College, Chicago. For the Use of Students. Second Edition. Detroit: George S. Davis, 1892. [The Physicians' Leisure Library.]

Aphasia due to Subdural Hemorrhage without External Signs of Injury; Operation; Recovery. By L. Bremer, M. D., and N. B. Carson, M. D., of St. Louis. [Reprinted from the *American Journal of the Medical Sciences*.]

Tobacco Insanity and Nervousness. By Dr. L. Bremer, St. Louis.

Annual Report of Surgical Operations performed by Horace Packard, M. D., Associate Professor of Surgery, Boston University School of Medicine, for the Year 1891, with a Report of a Third Series of Abdominal Operations, comprising Sixty-seven Cases.

Rupture of the Sac of an Extra-uterine Pregnancy through the Fimbriated Extremity without tearing the Fallopian Tube. Operation; Recovery. By Hunter Robb, M. D., Baltimore, Md. [Reprinted from the *New York Journal of Gynecology and Obstetrics*.]

Mme. Lachapelle, Midwife. By Hunter Robb, M. D., Baltimore. [Reprinted from the *Johns Hopkins Hospital Bulletin*.]

Treatment of Laryngeal Phthisis. By Robert Levy, M. D., Denver, Col. [Reprinted from the *Medical and Surgical Reporter*.]

Two Cases of Trephining for Traumatic Epilepsy. By Philip Coombs Knapp, A. M., M. D., and Abner Post, M. D., Boston. [Reprinted from the *Boston Medical and Surgical Journal*.]

Diseases of the Urinary Apparatus. Phlegmasic Affections. By John W. S. Gouley, M. D., Surgeon to Bellevue Hospital. New York: D. Appleton & Co., 1892. Pp. xiii to 342. [Price, \$1.50.]

The Medical Annual and Practitioners' Index: A Work of Reference for Medical Practitioners, 1892. Tenth Year. Bristol: John Wright & Co. Pp. lii to 667.

Accidents from the Electric Current: A Contribution to the Study of the Action of Currents of High Potential upon the Human Organism. By Philip Coombs Knapp, A. M., M. D., Boston. [Reprinted from the *Boston Medical and Surgical Journal*.]

A Case of Tumor of the Cerebellum in which Trephining was done for the Relief of Increased Intracranial Pressure. By Philip Coombs Knapp, A. M., M. D., Boston. [Reprinted from the *Journal of Nervous and Mental Disease*.]

Astasia-Abasia. With the Report of a Case of Paroxysmal Trepidant Abasia associated with Paralysis Agitans. By Philip Coombs Knapp, A. M., M. D., Boston. [Reprinted from the *Journal of Nervous and Mental Disease*.]

The Treatment of Epilepsy; with Special Reference to the Use of Potassium Bromate, Magnesium Bromide, Nitroglycerin, Antifebrine, Sulphonal, etc. By Guy Hinsdale, M. D., Philadelphia. [Reprinted from the *International Medical Magazine*.]

Thirty-second Annual Report of the Medical Superintendent of the State Asylum for Insane Criminals, Auburn, N. Y. For the Year ending September 30, 1891.

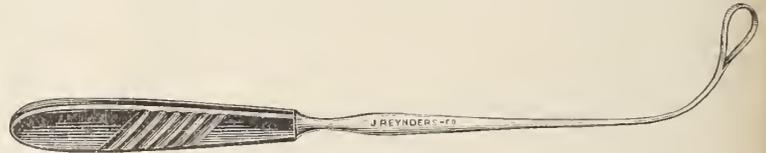

Removal of Superfluous Hair by Electrolysis. By F. J. Leviser, M. D., New York. [Reprinted from the *Medical Record*.]

### New Inventions, etc.

#### A LATERAL-CUTTING CURETTE.

By LEONARD A. DESSAR, M. D.

MESSRS. REYNDERS & Co. have made for me a curette which I find of great service in removing adenoid tissue from the lateral walls and vault of the pharynx, as well as from the fossa of Rosenmüller. The instru-

ment has but one cutting edge, the other being blunt, and two of them are required to entirely free the vault and sides of the pharynx of adenoid tissue. The curette is passed up into the vault close to the lateral wall and behind the arch of the palate. As the one edge is blunt, no injury can be done to the pharyngeal structures. A lateral sweep removes the adenoid growths from the vault and opposite side of the pharynx. The one curette cuts from left to right, the other from right to left.

### Miscellany.

**A Form of Painful Toe.**—The *Lancet* for March 19th contains the following article, by Dr. L. G. Guthrie:

The intense suffering caused by this complaint, and the prompt and certain relief which may be obtained by suitable yet simple treatment, lead me to record my own experience of a special form of painful toe. Both in symptoms and pathology the complaint is identical with that to which Dr. Auguste Pollosson, in 1889, gave the name "anterior metatarsalgia." Only in the latter the metatarso-phalangeal joints are affected, whilst in the former the distal phalangeal joints are alone involved. In order to avoid a more cumbersome designation I have called the former affection "a form of painful toe." In either case, under the influence of prolonged standing or walking in tight boots, the ligaments of one or more joints, metatarso-phalangeal or phalangeal only, become strained, slight subluxation takes place, the nerves are stretched and pressed upon by the partially dislocated bones, and the characteristic pain is produced. The pain occurs suddenly, and with a sense of something giving way at the site of the joint affected. It is relieved by taking off the boot and gently pressing the displaced bones into proper position. The reduction is always accompanied by a sharp twinge of pain, followed by instantaneous relief. I have only met with one case of the major affection. It was that of a tramear conductor, who suddenly developed the symptoms, and had suffered from them for three months

The pain was under the head of the third metatarsal bone, and he could relieve it by taking off his boot, flexing his toes while pressing gently with his finger on the site of the pain. His occupation prevented him from carrying out this treatment as often as he desired, so I directed him to wear a boot with a very broad sole, slightly convex on the upper surface, so as to support the sunken head of the third metatarsal bone, and with plenty of room across the base of all the toes. This treatment proved thoroughly satisfactory. The following are cases of the minor but similar affection—painful toe:

CASE I.—In the autumn of 1883, after a long day on duty as hospital dresser, I walked through the wet streets to the opera. The theatre was crowded, and I had to stand throughout the performance. Toward the close I suddenly felt most severe shooting and burning pain in the fourth toe of my left foot. The boring of a hot iron into the flesh might have caused similar pain. It extended up the nerves of the outer side of the foot and leg into the sciatic, with a numbing, sickening sensation. I limped home, with dismal misgivings lest I had fallen a premature victim to gout; but on taking off my boot I discovered that the last phalanx of the fourth toe was overextended, while the head of the second phalanx was slightly displaced downward. Reduction caused a sharp twinge of pain, followed by immediate relief. From this time for many months I was constantly liable to these attacks of pain, especially in hot, damp days, after standing or walking for any length of time. I learned to reduce the dislocation and obtain relief by treading heavily on the empty part of the toe of my left boot with the heel of my right, and then forcibly drawing the left foot back within the boot, at the same time elevating the toes against the "uppers." Both the displacement and the reduction were accompanied by a distinct click. This manoeuvre became necessary with more and more frequency, and the pain increased in severity until I had serious thoughts of having the toe amputated or the joint resected. At last, with the happy inspiration of Mark Twain's hero, who after twenty years' confinement opened his cell door and walked out, I discovered an equally easy means of escape. My boot, though quite comfortable when first put on, became too tight across the toes as soon as the foot became at all congested. Under this condition the last phalanges became jammed and fixed together, while the relaxed ligaments of the second joint of the fourth toe allowed the head of the second phalanx to drop and press painfully upon the nerves. I ordered a boot with plenty of room for lateral expansion of the toes, and I was at once freed from the attacks of pain which made my life a burden.

CASE II.—A gentleman recently consulted me on what he believed to be a soft corn between the fourth and little toe of the right foot. On examination, I could find no trace of the soft corn, but infantile paralysis had left his foot with slight talipes varus and marked pes cavus. The great toe was hyperextended and pointed outward at an acute angle from the metatarsal joint. The rest of the toes were crushed together in the form of a cone; the fourth toe was laterally flexed and almost hidden beneath the third. The calf muscles were wasted, and the limb was nearly three quarters of an inch shorter than the other. To counteract the shortening, he had worn for many years an extra three-quarter-inch heel inside his boot. The sole was not similarly raised, so he was compelled to walk in a downward plane, forcing his toes together at each step into his somewhat pointed and short boot. He suffered no inconvenience from these deformities until the beginning of the year 1891, when he acquired the habit of walking on the outside of his foot, bearing especially on the outer side of the little toe, in order to avoid resting his full weight on the ball of the great toe, which was unduly prominent and tender. In July, 1891, during a long walk, he was suddenly attacked by acute pain in the little toe. The sensation, he said, was as if a hot fusee were placed between his toes and were burning slowly outward through the little toe. From that time until I saw him three months later he had been constantly subject to these attacks of excruciating pain, and they had so increased in frequency and severity that he said he would have his toe amputated at once if he could not otherwise obtain speedy relief. He could wear a loose slipper with comfort, but on walking in a boot for even a few yards the pain occurred. It was not relieved by taking off the boot, but he showed me how, on gently pressing the tip of the little toe outward, the pain instantaneously ceased, the manoeuvre being accompanied by an extra sharp twinge of pain. Obviously his suffering

was due to slight inward displacement of the last phalanx of his little toe, and consequent stretching and compression of the nerves between the displaced bone and the adjoining toe. The treatment in this case was not so simple as in my own, owing to the various deformities of his foot. But, to make the story short, complete relief was obtained by a boot contrived on the following principles: Plenty of room was given across the toes, the little toe being especially relieved of all pressure. The outer side of the fore part of the sole was raised and the heel lowered, so as to throw his weight from the outer to the inner side of the boot, and to prevent forcing of the toes together. A graduated depression was made beneath the ball of the great toe in order to avoid walking on the downwardly displaced head of his first metatarsal bone.

Remarks.—These cases form additional links in the chain of evils attendant on wearing boots too tight across the toes. Patients will be probably loath to admit that a form of boot to which they have always been accustomed, and which they have regarded as both comfortable and elegant, can be the cause of their sudden attacks of pain. And the latter they will readily attribute to gout or rheumatism; for to the non-professional public, pain in a toe means gout, and pain elsewhere in a limb means rheumatism. Not only do the paroxysms of pain strongly resemble those of gout, but it is possible that the strained and unnatural position into which many force their great toes may account for the prevalence with which those parts become the primary seat of true gout.

**An Appreciative Notice of American Pharmaceutical Preparations.**—The *Lancet* for March 26th says:

Some years ago we had occasion to report favorably upon certain admirable products of this firm, and recently we have had submitted to us further interesting and new preparations, the results of the examination of which are well worthy of record. Liquid panerobilin, as its name indicates, contains the agents which prepare food for assimilation in the duodenum. It is a clear, syrupy, brown fluid, slightly alkaline to test-paper, and sweet at first to the taste and then persistently bitter. After acidulation with sulphuric acid, ether extracted a body which gave the well-known bile reaction with strong sulphuric acid and syrup (Pettenkofer's test). Emulsion of starch was readily liquefied, and slowly though distinctly converted. According to other reactions, the preparation contains glycerin and spirit. On suitable treatment, the panerobilin pills gave reactions confirmatory of the presence of both constituents—ox bile and pancreatin; while from the compound panerobilin pills—into the composition of which nux vomica, damiana, extract of colocynth, and quinine enter—the alkaloids of nux vomica and quinine were successfully extracted and identified. Lacto-preparata is described as artificially prepared human milk and sterilized, in which the tough character of the caseine is so modified that it will no longer coagulate into hard curds. It has probably therefore been malted or partly digested with diastase, for under the microscope a few cells of barley starch were recognized. On analysis, lacto-preparata gave the following results: Moisture, 1.7 per cent.; fat, 0.6 per cent.; mineral matter, 5.2 per cent. (mainly phosphate of potassium); sugars and albuminoids, 92.5 per cent. Lacto-cereal food is a somewhat complex mixture, and consists of partly digested milk powder, starch, dextrin, malted barley, desiccated bananas, cacao butter, and manna. It is characterized by a very agreeable flavor, and evidently contains a rich proportion of nourishing and probably easily digestible materials. Still more novel are the kuuysgen tablets made by this firm, which, when dissolved in water, yield a kind of effervescing kuuys (koumiss). The tablets consist of small cylinders which slowly dissolve in water with effervescence, and by putting twelve in a bottle of water provided with a screw stopper, an effervescent milk may be obtained. The liquid so prepared is sweet and resembles fresh milk. The greater part of the caseine is apparently in solution, as, on addition of acid, clots at once separate. These preparations furnish unmistakable evidence of the desire on the part of the manufacturers to place in the market products of a highly scientific kind, and, this being so, we may confidently recommend them to the notice of the profession.

**The Use of Gelatin Discs in the Eye.**—A paper was read before the Philadelphia County Medical Society on March 23d by Dr. John S. Stewart, Ophthalmic Surgeon to the Philadelphia Lying-in Charity, in

which he said that some excuse, perhaps, might be needed for bringing before the Society a subject which could be of practical interest to specialists of one department only; but it had occurred to him that a very brief account of one of the methods of applying medicaments to the eye, which, in his hands at least, had proved highly satisfactory, might be not altogether devoid of interest even to those engaged in other lines of work. He referred to the use of medicated gelatin discs, and would consider only the advantages of applying homatropine and cocaine to the eye by this means. Four years ago, in the article on Homatropine, published in the *Medical News*, he had called attention to the fact of having frequently observed an irritant action exerted on the deep structures of the eye by repeated applications of a watery solution of hydrobromide of homatropine. At that time it had been his belief that this irritation was the principal cause why ametropia could not be accurately estimated in very many cases where homatropine had been employed, and a considerable experience since in the use of watery solutions of the drug had tended only to confirm this opinion. That irritation was produced in every instance by this method of practice he did not pretend to say; but he was convinced that in all cases where there had been considerable and long-continued eye-strain, resulting from efforts to overcome particularly aggravating forms of refractive error, or where chorio-retinal irritation, due to other causes, existed, the homatropine as ordinarily used very often added to the intra-ocular disturbance, and thereby interfered with the attainment of the object for which it was employed—viz., the accurate estimation of the refraction of the eye.

Another objection which he had to the use of watery solutions of this drug was that a large proportion of the effect was expended on the nasal and pharyngeal mucous tract rather than on the eye, as intended. There was no doubt in his mind that both the irritant effects on the eye and the, at least, unpleasant ones on the nose and throat were directly due to the necessarily strong solutions employed—ranging, so far as he had been able to learn, from eight to twenty-four grains to the fluidounce—instilled in most instances a number of times within an hour.

It was said that medicated gelatin discs for ophthalmic use were first made in 1863 by Savory & Moore, of London; but, strangely enough, they had never been extensively used. About five months before, he had begun to try some of those made at the suggestion of Dr. C. A. Wood, of Chicago, by Messrs. Wyeth & Brother, of Philadelphia, and almost ever since, when he had had occasion to use homatropine alone or combined with cocaine for the purposes of refractive work, he had much preferred these discs to the watery solutions formerly used by him.

On first thought it might seem unlikely that a single disc, containing one fiftieth of a grain each of homatropine and cocaine, could exert sufficient influence on the accommodative power; but he had, in most instances at least, found as nearly complete paralysis of accommodation as he had ever been able to obtain with repeated instillations of two and three-per-cent. solutions of homatropine. The reason was not hard to discover. Absorption of the drug by the tissues of the eye took place about as rapidly as the drug itself could be liberated by the dissolving of the gelatin; but when a drop of solution had been instilled, a large proportion necessarily escaped with the tears, or, if it did not get away so quickly, was quite likely to produce in sensitive eyes the chorio-retinal irritation which so often interfered with obtaining the results for which the drug was used.

Very few of his patients who had had these discs in their eyes could detect any effect whatever in the nose or throat, and in these few instances the information was obtained only by questioning the patients on the subject.

In his practice at the present time, in all eyes suitable for the use of homatropine and requiring its use for the purposes of refraction, he was making use of discs containing one fiftieth of a grain each of homatropine and cocaine—either the hydrobromide and hydrochloride respectively, or the alkaloid. He had found it an advantage, but not always a necessity, in the case of most patients under twenty-five years of age, to insert a second disc of homatropine only (one fiftieth of a grain) into each eye as soon as the first was entirely dissolved—usually in about ten minutes. A small camel's-hair brush moistened served conveniently

to convey the disc to the eye, and, although it had been recommended to place the disc against the scleral conjunctiva—in the grasp of the lower lid—he much preferred raising the upper lid and inserting the disc beneath it, immediately above the outer canthus, then directing the patient to keep the lids lightly closed as in sleep, and to avoid winking until the discs were dissolved.

It had been urged against the use of the gelatin discs that the lids and eyes were thereby rendered very sticky and uncomfortable. His patients had not complained of this; but he thought the annoyance had been escaped, in large measure at least, by strictly following his injunction about keeping the eyes closed.

As to the reputed advantage of the combination of cocaine with homatropine, he had little to say. It was said, of course, that homatropine combined with cocaine dilated the pupil and paralyzed the accommodation more rapidly and effectively than homatropine alone, and that these results were more permanent. This seemed usually to be the case; but cocaine was used by him in these cases because of the quieting effect which it produced on most eyes, thus tending, in some measure at least, to overcome the irritant effect of the homatropine, and at the same time to facilitate the measurement of the ametropia.

On several occasions he had used the English preparation of Savory & Moore, of London; but he had no hesitation in expressing a preference for the Wyeth discs.

**The Iowa State Medical Society** will hold its forty-first annual meeting at Des Moines on Wednesday, Thursday, and Friday, May 18th, 19th, and 20th, under the presidency of Dr. George F. Jenkins, of Keokuk. The preliminary programme includes the following titles:

*Section in Practice of Medicine.*—Report, by Dr. Edward Hornbrook, of Cherokee; The Body Temperature in Health and Disease, by Dr. Gresham H. Hill, of Independence; Observations noted in Two Cases of Congestion, by Dr. C. S. Chase, of Waterloo; La Grippe, by Dr. H. A. Wheeler, of Onawa; Was it Scarlet Fever? History and Recovery, by Dr. J. P. Savage, of Sioux City; The Year's Progress in Bacteriology, by Dr. J. B. Ingels, of Meriden; The Pathology and Bacteriology of Tuberculosis, by Dr. M. N. Volding, of Independence; What is it? Why is it? by Dr. O. B. Harriman, of Hampton; Tuberculosis, by Dr. A. L. Wright, of Carroll; Hay Fever, by Dr. E. S. Blair, of Correctionville; Practice *vs.* Materia Medica, by Dr. H. Newell Sill, of Strawberry Point; My Experience in Intubation of the Larynx, by Dr. J. W. Kime, of Fort Dodge; Diphtheria, by Dr. C. M. Drumeler, of Panora; Pneumonia, by Dr. N. Agnew, of Storm Lake; The Rational Treatment of Inebriety, by Dr. A. W. McClure, of Mt. Pleasant; Atropine Poisoning, by Dr. J. M. Emmert, of Atlantic; Pneumonia as a Complication of La Grippe, by Dr. A. C. Bergen, of Sioux City; Diarrhœal Disorders of Children, by Dr. H. E. W. Barnes, of Macksburgh; Thrombosis and Embolism in Practice aside from Surgery, by Dr. Mila P. Sharp, of Storm Lake; Catarrh of the Bile Ducts, by Dr. F. W. Powers, of Reinbeck; A Case of Pulmonary Tuberculosis, by Dr. W. C. Bundy, of Aurelia; Diphtheria, by Dr. Milo Avery, of Aurelia; Antipyretics in Continued Fever, by Dr. R. L. Cleaves, of Cherokee; also papers by Dr. C. J. Hackett, of Le Mars, Dr. P. J. Farnsworth, of Clinton, and Dr. J. H. Divine, of Sioux Rapids.

*Section in Surgery.*—Report, by Dr. O. J. Fullerton, of Waterloo; Surgical Regeneration, by Dr. R. E. Coniff, of Sioux City; Intestinal Obstruction, by Dr. J. R. Guthrie, of Dubuque; Orthopædic Surgery, by Dr. J. W. Cokenower, of Des Moines; The Surgery of the Rectum, by Dr. Lewis Schooler, of Des Moines; Laparotomy, by Dr. A. J. Hobson, of Bristow; Oils and Fats in Surgical Dressings, by Dr. C. M. Hobby, of Iowa City; The Management of Compound Fracture, by Dr. A. B. Bowen, of Maquoketa; Resection of the Intestine, by Dr. P. M. Jewell, of Ossian; and a paper by Dr. T. J. Maxwell, of Keokuk.

*Section in Materia Medica and Therapeutics.*—Report, by Dr. J. M. Barstow, of Council Bluffs.

*Section in Obstetrics and Gynecology.*—Report—The Present Status of Obstetrics and Gynecology, by Dr. E. H. King, of Muscatine; Uterine Fibroids, by Dr. D. C. Brockman, of Marengo; Some Diseases of the Ovaries and Results, by Dr. J. C. Schrader, of Iowa City; Three Cases of Ovariectomy, with Comments, by Dr. H. L. Getz, of Marshalltown; The Effect of Higher Education on the Women of To-day, by Dr. J. S.

Braunsworth, of Muscatine; Reflections on the Present Status of Gynecology, by Dr. J. H. Kersey, of Stuart; Removal of the Uterine Appendages for Epilepsy—Case, by Dr. C. E. Ruth, of Muscatine; Uterine Polypi, with Report of Two Cases, by Dr. T. P. Stanton, of Chariton; An Epitome of Obstetric Practice, by Dr. H. R. Page, of Des Moines; and a paper by Dr. J. A. Scroggs, of Keokuk.

*Section in Ophthalmology and Otolaryngology.*—Report, by Dr. J. W. Dalbey, of Cedar Rapids; Corneal Ulcers, by Dr. F. E. V. Shore, of Des Moines; Methods of Middle-Ear Inflation, by Dr. J. M. Ball, of Keokuk; and a paper by Dr. Woods Hutchinson, of Des Moines.

*Section in State Medicine and Hygiene.*—Report, by Dr. Calvin Snook, of Fairfield; State Care vs. County Care of the Chronic Insane, by Dr. G. H. Hill, of Independence; Local Boards of Health, by Dr. G. A. Spilman, of Ottumwa; The Nature of Immunity against Infectious Diseases, by Dr. C. E. Stoner, of Des Moines; and a paper by Dr. C. B. Powell, of Albia.

*Section in Diseases of the Mind and Nervous System.*—Report, by Dr. P. W. Lewellen, of Clarinda; The Influence of Mind as a Cause and Cure of Disease, by Dr. R. Sears, of Marshalltown.

**A New Use for Aluminium.**—On the 8th of March letters patent were issued to the firm of A. A. Marks, of New York, for artificial limbs constructed in part of aluminium.

This metal, with its unlimited uses, seems to be peculiarly adapted for surgical appliances, instruments, and artificial limbs; its low specific gravity and its great comparative strength are qualities that are desirable to be combined in an artificial leg or arm.

There are amputations of the lower limbs that surgeons deem desirable to do, without sacrificing more of the member than the parts involved. We refer to amputations technically termed tibio-tarsal, tarso-metatarsal, and medio-tarsal. These amputations have always been in disfavor with artificial-limb makers, who have almost unanimously decried them, and in too many instances have persuaded the surgeons to sacrifice much of a healthy leg merely to obtain a stump that would better accommodate the artificial limbs that they were able to produce.

The new artificial leg constructed of aluminium, combined with the rubber foot, is adaptable to these amputations. The socket of aluminium incases the stump, and, on account of the strength of the metal, the socket does not increase the diameters of the ankle to an objectionable degree in order to obtain the requisite strength; the metal is cast into the proper shape to give ease and comfort to the wearer; the aluminium socket is terminated by a rubber foot, which not only simulates the natural foot, but provides a soft, springy medium to walk upon and a resistant phalangeal ball to rise upon while walking, running, or ascending stairs.

It is obvious that by this invention the amputation can be conditional upon the injury, and the artificial limb conditional upon the amputation. In this alone the invention of the aluminium and rubber leg will prove not only a boon to the one who has suffered the amputation, but the solution of a problem that has many times perplexed the operating surgeon, as it eliminates all the objections heretofore pressed against amputations in the region of the tarsus. The surgeon may thus rejoice in being able to observe the old and consistent law of amputating with the least sacrifice.

Aluminium also plays an important part in the construction of strong and durable artificial arms. The socket of an arm made of that metal is light and strong, and will enable the wearer to subject the artificial arm to severe uses without danger of destruction. It will not crack from overstrain like wood, it will not become soft and limp or foul from perspiration like leather; it is lighter than any other metal, and is amply strong for every purpose.

**The Histological Lesions produced by the Toxalbumin of Diphtheria.**—The following article, by Dr. William H. Welch and Dr. Simon Flexner, appeared in the *Bulletin of the Johns Hopkins Hospital* for March:

In a preliminary communication presented to the Johns Hopkins Hospital Medical Society, and published in the *Hospital Bulletin*, No. 15, August, 1891, we called attention to the histological changes in the organs of animals which had died of experimental diphtheria, following

the inoculation of pure cultures of the *Bacillus diphtherie*. Since then we have extended our investigations so as to include the study of the lesions produced by the inoculation of the toxic products of the diphtheria bacillus. This study virtually finishes the work we have undertaken, and it is hoped soon to publish our results in detail. However, in order to make our preliminary communication complete, we append this report.

The toxic products of the diphtheria bacillus with which we have operated were obtained by filtering through a new and sterilized Chamberland filter a culture of the organisms in glycerin bouillon several weeks old. The fluid so obtained was tested by means of cover-slips and inoculations on glycerin-agar, and proved to be sterile.

Guinea-pigs were used for the experimental inoculations. The sterile culture fluid was introduced subcutaneously into the tissues of the belly wall. The method pursued will be given in connection with the case of which the lesions are to be described. This guinea-pig received on the 10th of December, 1891, 1 c. c. of the filtrate. Not having succumbed, on December 14th it received 2 c. c. more. The animal died on January 5, 1892, the duration of life since the first inoculation having been three weeks and five days, and since the last, three weeks and one day.

At the autopsy the vessels of the subcutaneous tissues were injected, and hemorrhage had taken place into the tissues of the axillary and inguinal regions. The subcutaneous tissues were moist, but there was no actual oedema present. Neither was there a visible area of localized inflammation. There was no microscopical examination made, however. The lymphatic glands of the axillary and inguinal regions were enlarged and reddened; the cervical lymph glands were swollen, and the thyroid gland was greatly congested.

There was a considerable excess of clear fluid in the peritoneal cavity. Both layers of the peritoneum were reddened, the vessels of the visceral layer being especially injected. The spleen was enlarged to double the average size. It was mottled, and the white follicles were distinctly outlined against the red ground. The liver was dark in color and contained much blood. On the surface a prominent yellowish-white area, 2 mm. in diameter, surrounded by a zone of hyperæmia, was observed. Smaller dot-like points of the same color and general appearance were seen elsewhere in the liver. The kidneys were congested, and the cut surface was cloudy. The adrenal glands appeared normal, as did the mesenteric glands.

The pleural cavity did not contain such a marked excess of fluid. The pericardial sac, however, was distended with clear serum. Under the epicardium were many ecchymotic spots. The lungs exhibited areas of intense congestion, or actual hemorrhage into the tissues. The glands of the thorax were, perhaps, swollen.

The examination of frozen sections showed the heart muscle to be slightly fatty. The epithelium of the tubules of the kidney was extremely granular and much swollen, but not fatty. The liver was very fatty; the lighter areas and dots were seen to correspond to foci of dead liver cells, whose refraction was much greater than that of the normal cells.

Cultures were made from the blood and organs of the animal, and they remained sterile. Cover-slips were also examined and no organisms found.

The histological lesions observed in this case are identical with those described by us in connection with the inoculation of the living organisms. Lymphatic apparatus: In general, the changes are the same throughout. They are found in the greatest intensity in the glands of the axillary and inguinal regions, and less in the bronchial, cervical, mediastinal, and mesenteric glands. Yet these are considerably affected. The same fragmentation of nuclei, affecting the lymph nodes and sinuses, is met with. These fragments exhibit the variety of form previously described by us, and they have the same affinity for coloring agents. Much of the nuclear detritus is free, but a part is contained within large pale cells. In the spleen there is a similar diffuse fragmentation of the nuclei of the spleen cells. Both the lymphoid cells of the follicles and the larger cells of the sinuses are affected. Like the lymphatic glands, some of the nuclear detritus is inclosed in large cells. Besides the destruction of cells in the spleen there is hemorrhage into the organ, or an extreme degree of congestion, so that the tissue elements are widely separated from one another. Nuclear figures

occur in the lymph glands and spleen. In the former they are found among the fragmented cells.

Stained sections of the liver, especially those stained in methylene-blue and eosine, show the yellowish-white areas to be composed of hyaline, necrotic liver cells. The necrotic cells stain deeply in the eosine, and they are usually devoid of nuclei. They form, on the whole, more or less definite foci of hyaline cells, into which leucocytes have wandered. The largest area was 2 mm. in diameter, and the outlines of it were formed by hæmorrhage into the tissues, corresponding with the hyperæmic zone spoken of above. The cells in this focus have lost their nuclei, and they are intensely refractive. Many of the dead cells have retained their individuality, and, indeed, their borders are more distinct than those of the normal cells. Others, however, tend to become fused together and to lose their individual cell outlines. Occasionally, outside the main focus of hyaline cells, single necrotic cells occur which are surrounded by quite normal ones. Many leucocytes have wandered into this area of dead cells, and they are especially abundant at one place in the focus in which the hyaline and necrotic cells are in process of disintegration. An exquisite nuclear fragmentation is to be observed throughout this area.

Should the focus just described be compared to many similar foci which occur in the livers of animals dead of inoculation with the bacilli themselves, it will be seen to contain more leucocytes (polynuclear) within it. The explanation of this fact would seem to depend somewhat on the incubation time, but more on the progression or stage of the necrotic process. Inoculation of the bacilli usually leads to death in a very short time, often in twenty-four to forty-eight hours. In this inoculation with the toxic products alone the incubation period exceeded three weeks. On account of this, time has been allowed for the softening and disintegration of the dead cells, and leucocytes have been strongly attracted to these foci.

In the kidneys, besides the condition described in the frozen sections, a slight fragmentation of the nuclei of the epithelium of the tubules is encountered. The lungs exhibit areas of hæmorrhage into the alveoli, and in many of these there has been a desquamation of the alveolar epithelium. Sometimes the desquamated epithelial cells are quite normal in appearance, while at others they have fragmented nuclei. The collections of lymphoid cells around the medium-sized and larger bronchi show, however, more cells, the nuclei of which have suffered in this way.

The blood-vessels of the tissues generally contain fewer leucocytes in this instance than in those cases in which the bacilli were introduced beneath the skin. By the latter method an intense local inflammatory process is provoked, associated with the emigration of large numbers of polynuclear leucocytes. In the former, in which the filtrate, free from organisms, is used for inoculation, the local process is reduced to *nil*, there is no emigration of leucocytes, and the disease is general from its inception. This difference is sufficient to account for the occurrence of leucocytes in the one case and its absence in the other.

It may be considered as established now that the toxic products and not the bacilli themselves invade the tissues in diphtheria. This fact would at once suggest that the general lesions (those produced at a distance from the seat of inoculation in animals, and the situation of the local process in human beings) were the effects of the soluble poison diffused through the body. Hence it was desirable to demonstrate this assumption experimentally; and it is not unimportant to know that the lesions in the tissues produced by the bacilli and the toxic principle on the one hand, and the toxic principle alone on the other, are in perfect correspondence with each other. And, moreover, it would seem not to be superfluous to emphasize the occurrence of definite focal lesions in the tissues of the body, produced by a soluble poison circulating in the blood.

**Artificial Teeth from a Hygienic Point of View.**—"It is common experience among dentists," says the *Lancet*, "that a very large majority of artificial dentures worn are discolored and by no means devoid of unpleasant odor. This lack of cleanliness, which arises sometimes from neglect, but often from want of instruction on the part of the dentist as to the necessary *modus operandi*, is a fruitful cause of inflammatory conditions. Debris of food mixed with saliva and mucus

accumulating on a plate rapidly undergo decomposition, with the result of irritating the mucous membrane and producing a general inflammation of the oral cavity. The oral secretions become altered and vitiated, so as to cause dyspepsia, and caries of the remaining natural teeth is set up, which proceeds with great rapidity, especially in 'clasp' dentures, not from the friction, but because the inside of the clasps most generally escape the brush. The materials used in the construction of artificial dentures differ widely in their effect upon the tissues with which they come in contact. A larger number of cases of inflammation of the oral tissues occur where vulcanite is used as a basis than with gold or other metals, and so prevalent is this inflammation in the case of vulcanite that it has received the distinctive appellation of 'rubber sore-mouth.' Several reasons have been assigned for the effects produced by vulcanite. Nearly all this material is colored with mercuric sulphide (vermilion), which ingredient has been accused of being the cause of trouble; but an exhaustive investigation did not substantiate this view, one particular point being that 'rubber sore-mouth' often occurred where black rubber was used, which contains no vermilion. The porosity of vulcanite, especially when not sufficiently vulcanized, renders it liable to retain deleterious material if not kept scrupulously clean."

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

STATISTICS OF  
OPERATIONS UPON TUBERCULOUS HIP JOINTS.\*

BY CHARLES T. POORE, A. M., M. D.,

SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN, NEW YORK.

THE following paper is based upon sixty-seven cases of tubercular disease of the hip joint occurring in children from three to fifteen years of age, being all the cases operated upon from 1873 to January 1, 1892, and occurring in hospital practice.

Sixty-five joints were excised; in five, erosion was performed; in eight cases the trochanter major was trephined; and in eleven cases the central cavity of the femur was cleaned out. In all the cases of excision the disease was more or less pronounced, and always accompanied by abscess.

It has been the rule to open all abscesses as soon as discovered, and explore the joint if the disease is marked; the parts were scraped or excised, and of late all tubercular tissue has been removed as thoroughly as possible.

The joint was entered in fifty-one cases by the old excision over, or behind, the trochanter major and the diseased parts were removed. In the earlier cases the upper part of the femur was thrown out through the wound and the parts divided with a saw. Later, the bone has been divided *in situ* with a sharp osteotome and the head and neck then removed; the disturbance of the soft parts is much less by the latter method.

For the last eighteen months I have used the flushing gouge advocated by Mr. Barker, of London. It consists of

a Volkmann's spoon, with a perforation through the handle and opening in the bowl of the spoon. The dotted lines in the cut represent the perforation. The other end of the metallic portion protrudes beyond the handle, and is provided with a button for the attachment of a long piece of rubber tubing; it has also a binding screw for the purpose of clamping the end of the tubing to the button. The instrument was copied from a cut in the *British Medical Journal*, 1889, vol. i, p. 123, the only changes being the addition of the binding screw and the omission of the cut-off.

A long piece of India-rubber tubing, attached to the end of the gouge, goes to a vessel of sterilized water, in which is dissolved some boric acid; the vessel is raised higher than the operator, so as to give force to the current. As the infected tissues are scraped away by the spoon, they are swept out of the wound by the flow of water; further, the hot water tends to control hemorrhage. I have found that this instrument affords a ready means to scrape and clean out, not only joint, but abscess cavities.

In all recent cases the capsule and all infected tissues have been removed as thoroughly as possible, the acetabulum scraped, and carious bone about its rim removed. The parts were then flushed with mercuric solution (1 to 1,000), the wound partially closed with deep and superficial sutures, leaving a large opening leading to its deepest portion; this was stuffed with iodoform gauze, and over this the usual bichloride dressing. I have never seen any advantage in closing up entirely the wound, or only leaving a small opening for a drainage-tube. Whenever it has been done, suppuration and an accumulation of tubercular tissue in the cavity left by the removal of bone has followed. It is difficult to get away all infected tissue, and I doubt whether it is ever accomplished; and a good, free exit for such material is an advantage. I have also discarded the use of drainage-tubes, trusting to ample openings and iodoform gauze, and I think that my wounds have acted better since adopting this method; at least there has been less after-ereetting than formerly. There is another point gained by this method, and, that is, we get a good firm cicatrix above the truncated shaft which not only binds the femur to the pelvis, but also prevents, to some extent, the riding upward of the shaft when any weight is borne by the limb.

In fifteen cases access was gained to the joints by an anterior incision (Schede) made "on the outer side of the crural nerve, a little below and half an inch internal to the anterior superior spine of the ilium, and passing vertically downward four or five inches. The internal border of the sartorius is first exposed, then the rectus, outer border of the ilio-psoas muscle," or the incision may be made from the outer side and just above the anterior superior spine of the ilium downward on to the capsule of the joint. I think that the latter incision gives more room. The advantages of this incision are many: it readily exposes the joint without much disturbance of the soft parts; it gives a better view of the capsule, bone, and surrounding tissues. The joint can be cleaned out more readily than by the lateral incision, and it is the only method by which an erosion can be done without great displacement of the head and neck.

I have adopted it in all cases except those in which there are extensive sinuses behind and below the hip, or where there is reason to expect profound changes in the articulation. If, after gaining access to the joint by this method, a lateral incision is demanded, it can be made without any disadvantage to the patient. In regard to drainage after this way of reaching the joint, if thought necessary, a rubber tube can be passed out behind; but I have seldom used one. Thorough enretting and flushing out with hot water with partial closing of the wound and stuffing the rest with iodoform gauze has, in the majority of cases, prevented any accumulation of matter. If the case seemed to demand better drainage I would prefer to make an ample incision behind the joint and then keep it opened with iodoform gauze, discarding the use of a drainage-tube.

In my early operations the wounds were stuffed with balsam of Peru and oakum, then carbolized gauze was used; now all wounds are dressed with iodoform gauze.

\* Read before the New York Surgical Society, December 24, 1891.

In the early cases considerable elevation of temperature was the rule, in the later the exception; in the former class considerable suppuration always followed the operation; in the latter it has been much less, and, in some cases, entirely absent, depending upon the amount of disease and the thoroughness with which infected tissues could be removed. In many old-standing cases a comparatively clean operation is an impossibility, and suppuration, often profuse, must be expected, and in this class the advantage of a large drainage opening is great as affording ample room for the escape of pus and infective material.

The after-treatment is as follows: As soon as the patient is returned to bed, extension and a long splint extending from the axilla to the middle of the leg is applied, so as to keep the limb at absolute rest, and these are kept on until the wound has closed, the packing being removed and reapplied as often as required. Considerable oozing and bloody serum will saturate the dressings for a day after the operation, but after that, if the case goes on well, the discharge is slight. If at any time tubercular granulations make their appearance, the patient should be placed under ether and the parts thoroughly everted, any suspicious point being removed, either in the bone or soft parts.

If there are abscesses in the soft parts about the diseased joint, their cavities should be thoroughly everted with a flushing gouge and drained independently of the joint cavity if possible.

*Statistics.*—In sixty-four cases only one joint was involved, and in three both.

The head and neck were removed in thirty-six cases, and in twenty-four the section was made below the trochanter major. The head alone was removed in seven cases.

There were extensive bone lesions in thirty-six cases, while in the remainder the disease was limited to the head alone.

The condition of the parts removed varied from extensive infiltration and softening of the bone, with perforation of the acetabulum, to simple caries of the head or tubercular abscess.

In fifteen cases loose bone was found in the cavity of the acetabulum, and in seven the head of the femur was detached. In five of the latter cases the operation consisted only in the removal of the loose head and curetting the cavity. In four cases there was pathological dislocation of the head of the bone, or what remained of it, on to the dorsum of the ilium, and in three of these the end of the femur was ankylosed in this position, dead bone being imprisoned by the new tissue forming the bond of union between the shaft and the pelvis.

In eleven cases the acetabulum was perforated, and in nine intrapelvic abscesses were present. In one case the gut and bladder were perforated by the abscess; in one only the gut, at what point could not be made out, but it was probably low down, as in one well-formed faeces passed out through the wound, while in the other water passed from the perforated acetabulum out through the anus.

Secondary abscesses formed in quite a number of cases, especially those in which the wound had been closed by sutures and drainage-tubes used.

In ten cases the end of the bone had to be re-excised

after some time, and in thirty-five cases old sinuses everted on account of the appearance of tubercular granulations.

Simple erosion has been performed in five cases, and by this I mean that the joint has been opened by the anterior incision, the capsule removed as thoroughly as possible, but no bone operation of any magnitude done, the flushing gouge and scissors being alone used. Of these, only two patients have recovered without a regular excision, the remaining three coming to that operation.

The ultimate result in sixty-six cases is as follows. By cure is meant that all sinuses have closed and there is no symptom of trouble about the hip; by relieved, that sinuses are open:

There were thirty-two children discharged *cured*, twenty-five died, three discharged relieved, two discharged not improved, and four in the hospital.

Of those discharged relieved, in one the ultimate result is unknown, one died from causes not connected with the joint, and one, when last heard from, was evidently affected with amyloid degeneration.

Of those discharged not improved, one died shortly after leaving the hospital, and in one the result is unknown.

Of the cause of death, fourteen died from amyloid degeneration, one from amyloid degeneration and peritonitis, two from general tuberculosis, one from acute nephritis, one from septicaemia, one from heart failure, one from oema (uraemic), three from meningitis, and one from exhaustion.

In three of the fatal cases the wound was soundly healed and the children had the use of the limb some time before their death.

In one case the knee joint on the opposite limb had to be amputated on account of advanced disease of that articulation. The time that elapsed from the time of operation to the date of death varied from one day (the case of heart failure) to five years, the average being seventeen and a half months.

Of the cases of perforation of the acetabulum, seven patients died and four recovered.

Of the two patients with perforation of the gut, one died from heart failure soon after the operation; the other recovered and has had no further trouble. He has been out of the hospital for three years, and is well.

*Shortening.*—There are two factors going to make up the amount of actual shortening of the limb:

1. That dependent on the disease—atrophy and arrested growth.

2. The amount of bone removed.

The first may amount to more than that due to the real shortening of the femur from the removal of bone. Thus, in a case not operated upon, the limb, after ten years, is three inches shorter than the sound one.

Second, that due to the amount of bone removed. This is always equal at least to the extent to which the shaft is shortened, depending upon the point of section.

There must be some loss in the actual length of the limb, even when the head alone is removed.

I can only find the shortening recorded in fifteen cases,

and at the time of discharge from the hospital it was as follows:

In three cases it was three quarters of an inch, in five an inch, in two an inch and a quarter, in two an inch and a half, in one an inch and three quarters, in one two inches, and in one four inches.

There is another factor that contributes much to the difficulty in walking, and that is the riding upward of the end of the femur upon the pelvis when any weight is borne upon the limb and increases practically the shortening. This riding upward is due to the loose connection of the end of the femur with the pelvis. It sometimes amounts to more than the actual shortening, as measured from the anterior superior spine of the ilium to the malleolus, but it varies much in different cases. I depend upon two factors—first, when the section is made; and, secondly, the amount of cicatricial tissue formed about and above the truncated shaft of the femur and its condition. If only the head of the bone has been removed, the neck, unless it has been pulled away by too heavy an extension weight, will be confined in the cavity of the acetabulum by new connective tissue, and no riding upward can take place. On the other hand, if all the neck has been removed, and, further, if section has been made between the trochanters, there is nothing to prevent this displacement every time weight is thrown upon the limb but the amount and condition of cicatricial tissue around and above the end of the bone. For this reason I think that the more of this kind of a buttress is formed above the point of section, and the more compact it is, the more useful will the limb be. Therefore no attempt should be made to obtain immediate closure of the whole wound. It may appear to be more brilliant surgery, but, from my own experience, it is a detriment to the patient. There is another practical point—namely, not to keep the end of the bone away from the line of acetabulum by too powerful extension, or the cicatricial tissue formed will afford too lax a bond of union between the end of the bone and the pelvis, and a flail-like joint will be the result. A strong hip splint should be worn for at least one year after a cure, in order to prevent the new-formed tissue from being elongated.

Of the patients discharged cured, the present condition of twenty-three is absolutely known: One is well eighteen years after discharge; one is well eleven years after discharge; two are well nine years after discharge; one is well seven years after discharge; two are well six years after discharge; one is well five years after discharge; one is well four years after discharge; one is well three years after discharge; four are well two years after discharge; nine are well one year after discharge.

The amount of shortening in some of these cases has increased, while in others there has been but little, if any, change. One patient at the time of discharge had one inch shortening; in eight years it has increased to two inches and a half; one patient at time of discharge had an inch and a quarter shortening, in eighteen months had an inch and three quarters; one patient at time of discharge had an inch and a half shortening, at the end of six years two inches and half shortening; one at time of discharge had an inch and a half, at the end of one year an inch and a half; one

at time of discharge had an inch shortening, at the end of five years had an inch and a half; one at time of discharge had an inch shortening, at the end of two years had an inch and a half; one at time of discharge had an inch shortening, at the end of eighteen months had an inch; one at time of discharge had three quarters of an inch shortening, at the end of three years had an inch and a half; one at time of discharge had four inches shortening, at the end of fourteen years had seven inches shortening.

In the patient who at the time of discharge had four inches shortening, at least half of this was due to atrophy of the limb and arrest of growth. He now has seven inches shortening. For a time he wore a high shoe and would get along with but little difficulty, but he has discarded its use, and now goes about with the aid of a crutch. He is able to bear his weight on the limb and has considerable power over it.

The usefulness of a limb after excision of the hip joint depends chiefly upon the strength and firmness of the attachment of the end of the femur to the pelvis; the shortening, provided it is compensated for by a proper high shoe, is not the main impediment to easy walking.

Among the lower classes it is often impossible to prevail on the parents of these children to provide and keep in repair a high shoe, and they go about either walking on their toes with the foot in a position of talipes equinus, or, if the deficiency is great, with a crutch or cane, so that the best result of the operation is not obtained.

In those cases where much bone has been removed and where extension has been so great that the bones have been kept far apart, there is great danger that a flail-like joint will result, with no power in the limb to bear weight; a crutch is a necessity. On the other hand, if the parts have been kept in good apposition—that is, the truncated end of the femur well up—a flail-like joint is the exception. Some of my cases, I know, use a crutch; a few from necessity, but with most of them it is due to the fact that they have discarded their high shoe.

There is always some limp, a sinking down of the side of the body on which the operation has been performed, due often to the instability of the support. Notwithstanding this, most of them are able to get about without discomfort. In some cases there is no riding upward of the shaft, while in others it is the chief cause of the difficulty in walking. In many cases most of the normal motion of the limb can be performed while the patient is on his back, while in others flexion is difficult. The limb is certainly not so good as one ankylosed at a proper angle. A successful erosion gives as good a limb as after a cure by the expectant method of treatment.

Cases in which the acetabulum is perforated are not hopeless, provided good drainage is afforded, and this can only be obtained by an excision, the section being made below the trochanter major, no matter what may be the condition of the head. The presence of anyloid degeneration is not a contra-indication to excision, but rather an indication for it, provided the soft parts are not completely riddled with abscess and the bones profoundly diseased; in such a case an amputation affords the best chance for saving

life. Disease of the pelvic bones is of grave import, and these cases usually terminate fatally in my experience.

There are two operations connected with disease of the hip joint that I wish briefly to refer to—namely, trephining the trochanter major and neck, and cleaning of the medullary cavity of the femur.

Macnamara and others, a few years ago, drew attention to the fact that it was possible in cases of hip-joint disease beginning in the neck to trephine the neck through the trochanter major, and either remove the point of disease or afford drainage to the bone, and thus prevent the joint from being infected.

I have performed this operation upon eight children. The indications are symptoms pointing to disease beginning in the bone, such as painful spasm and night cries, the articulation itself not being involved.

The operation is easily performed by making an incision over the trochanter major, and then applying a three-eighth-of-an-inch trephine, so as to perforate the center of the neck as far as possible without entering the joint.

This is then flushed out with mercuric solution, a small Volkman spoon passed in to discover if possible any soft point, then a drainage-tube and iodoform, and, over all, the usual dressing applied.

In four cases diseased bone was found; in the other none. The immediate effect of the operation is always to stop night crying and spasm, and diminish the tenderness about the joint. The ultimate results were as follows: In two there was no return of any disease; the patients made a rapid recovery and have remained well ever since. The six other cases came to an excision, the pain after some weeks returning and the disease following its usual course. In the two patients discharged cured their histories were such as to leave no doubt as to the nature of the disease—articular osteitis. In some of the other cases I am now satisfied that the joint was involved at the time of the operation, and that it had been delayed too long. Recently I opened an abscess on the outer aspect of the thigh in a case in which I had trephined the neck two months previous. On tracing up the abscess, it was found that it had its origin in the trephine cavity, and from it protruded tubercular tissue; with a small spoon tubercular bone was removed. It is reasonable to suppose that the tubercular foci in the bone were finding an outlet through the trephine opening, and not into the joint. I think that my error has been in not operating earlier. The operation is certainly devoid of danger.

*Cleaning out the Central Cavity of the Femur.*—In some cases of joint disease, after the removal of the head and neck, the cut surface of the shaft presents a dark appearance, the bone is soft and infiltrated, the periosteum is thickened and easily detached, so that the whole shaft can be easily forced out through the wound, leaving the periosteum intact. If the medullary cavity of the femur is reached by the section, it is found filled with dirty, dark-colored material; the external shell of the bone is thinned, of a dark color, and soft. In cases where this condition exists the upper portion of the wound may do well, but a sinus, often several, will persist, through which the cut end of the

femur can be felt more or less eroded and from which the periosteum has retracted. If the wound is opened and a section made farther down, the same unhealthy condition will be found, and in a short time the cut end of the femur will present a condition and appearance the same as before. The wound will seldom close, and after a time amyloid degeneration shows itself, followed by a fatal termination. Since 1884 I have in all such cases made an opening into the shaft of the femur on its outer aspect just above the knee joint. Exposing the medullary cavity, a long probe, to which is attached a piece of silk thread and to this a long strip of iodoform gauze, is drawn through the whole length of the cavity in the bone so as to thoroughly remove its contents; it is then flushed out with bichloride solution, iodoform dusted in, a drainage-tube inserted in the lower opening, and the wound in the soft parts closed, except where the drainage-tube protrudes. The result of this operation is that all the diseased tissue is removed from the medullary cavity of the femur, and, unless there are other causes at work, the wounds close and recovery follows.

In twenty-one cases this condition of the shaft of the femur was found; in eleven, the central cavity was cleaned out, and in ten no operation was done; in the ten latter cases, eight patients died and two recovered. Of the eleven patients treated as above described, two died and nine recovered, one of the patients dying from heart failure twenty-four hours after the operation; the other, three years later, from amyloid degeneration, the femur giving no further trouble. By recovery is meant that the excision wound healed.

In one of the cases of recovery the whole shaft became enlarged, but has never given any discomfort.

## ERUPTIONS FROM IODIDE OF POTASSIUM,

WITH REPORT OF

A CASE OF DERMATITIS TUBEROSA FROM THE IODIDE.\*

BY GEORGE D. HOLSTEN, M. D.,

ATTENDING PHYSICIAN FOR DISEASES OF THE SKIN,  
BROOKLYN (E. D.) HOSPITAL DISPENSARY.

THE study of eruptions produced by the ingestion of various drugs has made rapid advances during the past few years. Among these drugs iodide of potassium occupies a prominent position, both on account of its frequent employment and because of its tendency to produce eruptions, whether given in large or small doses, or for a long or short period of time.

Iodide of potassium may produce a great variety of eruptions, the recognition of which becomes of importance, as the drug is employed so frequently in syphilitic as well as other affections, and failure to distinguish between a syphilitic or other eruption and one caused by the iodide may be of serious consequence to the patient.

The history of a case lately under my care is as follows:

\* Read before the Society of the Alumni of Charity Hospital, March 2, 1892.

G. H., aged sixteen months, was taken sick with symptoms of coryza, followed by bronchitis, for which, among other remedies, a saturated solution of iodide of potassium, two drops every two hours, was ordered on April 5th. On the 8th an eruption of small, isolated, conical-shaped, light reddish-brown papules appeared on the face and extremities. The eruption increased in amount and the individual lesions in size. I first saw the case on April 23d. During this time the general health of the child had improved; the coryza and bronchitis had disappeared, the appetite had returned, and, except for the eruption, he was entirely well. The iodide had been continued up to about a week before I first saw him, and altogether less than a drachm and a half of the drug had been taken.

The lesions appeared on the face and extremities, none on the body. On the face they were on both cheeks and a few on the forehead; there were also a few small spots on the sides of the neck. Both arms and forearms from shoulders to wrists were occupied by lesions, as were also both lower extremities from hips to ankles. The hands and feet were free. On the legs the lesions were equally numerous on the posterior as on the anterior surfaces, while on the thighs only the anterior surfaces were affected, and much less than the legs, as regards both number and size of the individual lesions. The upper extremities showed more lesions on the arms, both posteriorly and anteriorly, while on the forearms the lesions were few.

The eruption was observed in all of its stages of development, from a small pin-head papule to a lesion an inch in diameter and half an inch in height. The eruption began as small elevations on the skin, most of them being of nearly normal color; others slightly pinkish and some white. To the touch they felt solid, and were movable with the skin, but gave the impression of being deeply seated. There was no surrounding erythema. Lesions beginning as vesicles or pustules were not seen.

As the papules became larger they began to flatten on the top, the border became smoothly rounded, the entire lesion was raised above the surrounding skin, and the surface was smooth and shining; the color varied from pink to yellowish-brown. When the lesions reached the size of a split pea the surface would become studded here and there with minute whitish specks, more numer-

FIG. 2.

of thin white fluid exuded. The largest of these tumors was on the outer side of the left leg (Fig. 1) and measured about an inch and a half by an inch, and over half an inch in height. It was oval in shape, the surface smooth and shining, and of a dark-red color. This was studded with a large number of these minute pustules. Pressure over the growth did not squeeze out any

fluid, but on puncturing these individual specks, minute drops of whitish fluid exuded.

Two days later all of the lesions, and especially the smaller ones, had increased very much in size; some had doubled; otherwise their appearance was as before.

On the 27th of April the smooth covering of the growth on the leg had come off, on removal of a mercurial plaster which had been applied, and small openings discharging pus were present; several days later this tumor presented a fungating appearance, being composed of small, round, dark-colored, fleshy projections, between which pus welled up on pressure. These fleshy projections bled easily on being touched. Several of the other growths on this left leg went through the same process as this one just described, but remained smaller in size.

The accompanying photograph (Fig. 2)—taken May 6th, a month after the iodide was first given, and more than two weeks after its cessation—shows several minute lesions on the legs which have appeared during the past week. These, beginning as papules, soon after formed a tiny vesicle on each of their apices which in a day or two changed into a pustule, but the solid character of the lesion beneath always remained evident.

The large lesions on the leg had assumed a fungoid or cauliflower appearance; the papillary growths were bathed in pus, which welled up alongside of them, and they bled easily on pressure or handling.

A week later the larger lesions on the face had become distinctly flatter, looking like patches of roughened leather set on the skin.

The treatment used in this case was: On the lower extremities, first a mercurial plaster, but this was soon discontinued and the growth destroyed by repeated applications of dichloroacetic acid. To the face, applications of ichthyol in watery solution were made, using at first a six-per-cent. solution which was subsequently increased to thirty per cent. This was also applied to one arm. As the lesions on the face and upper extremities were nearly the same as regarded size, appearance, and character, the right arm was left untreated for some time in order to observe the natural course of the disease and for purposes of comparison.

FIG. 1.

us around the periphery of the papules. These specks varied in number, being proportionately more numerous on the larger lesions, although there were some on which no such white specks could be seen. On puncturing these specks a minute quantity

of pus was exuded. In every instance the lesions treated with ichthyol solution healed more rapidly than those not so treated. Some of the lesions were also treated with salicylic acid in ointment and also in collodion, but, while this

removed the horny portion of the epidermis, it had no effect on the deeper portion of the lesions. The involution of the smallest lesions, which were not treated, was very slow. The action of the dichloroacetic acid was not altogether satisfactory; the amount of tissue destroyed was superficial, making repeated applications necessary. As the lesions extended deeply into the corium, scars were a natural sequence, but, as they now are smooth and show no tendency to contract, that feature offsets the superficial action of the acid.

The most usual form of eruption produced by iodide of potassium is one resembling ordinary acne, but differing slightly from that disease in appearing not only on the face, shoulders, back, and chest, which are the seat of acne vulgaris, but also on other portions of the body—the extremities—and in the individual lesions being smaller and without induration; in the contents being thinner in consistence and the tops more acuminate—differences, though very slight, still sufficient to cause an inquiry as to whether the iodide had been taken or not. They also resemble the acneform eruption of bromide of potassium, but are slightly smaller; the reddened base is generally absent, but when it exists the pustules are more acuminate than in bromide acne.

Vesicular and bullous eruptions are among the rarer forms of skin lesions. The vesicles may be preceded by an erythema, as in a case of Bérenquier's (1), in which numerous small discrete vesicles seated on a bright scarlet surface had appeared suddenly.

The bullous form is more infrequent than the vesicular. Morrow (2) has reported an interesting example seen by him at Charity Hospital, in a man aged fifty, who had, three days after beginning the use of the one-in-two solution of iodide of potassium, a drachm three times daily, an erythematous condition of the face with vesico-pustules. The drug being continued, the dermatitis increased and the vesicles developed into bullæ. Ten days later the face and neck were bright red and swollen, and the integument was infiltrated; the eyelids were œdematous, preventing the eyes from being opened, and the ears were swollen and covered with crusts from ruptured bullæ; the forehead was thickly studded with pustules. On the dorsal surface of the hands and wrists there were several bullæ, one on the right hand being as large as a pigeon's egg and surrounded by smaller ones. The mucous membranes were free.

McGuire (3) has reported a case of bullous eruption due to iodide of ammonium. After about twenty grains of the drug had been taken a vesicular eruption appeared on the scalp, face, and shoulders, which disappeared in a few days on discontinuing the medicine. Two weeks later the iodide was again given, and after four doses—in all, five grains—had been taken, the eruption reappeared and attained its maximum development in ten days after the drug was finally discontinued.

The special characteristics of this form are the development of bullæ of varying size, commingled with vesicles and pustules. Usually beginning as minute vesicles on an erythematous surface, they increase rapidly and develop into regularly rounded or globular bullæ, which may remain single or coalesce with neighboring ones until they attain

an enormous size. All portions of the body have been the seat of this bullous form.

Besides the varieties already mentioned, others have been seen and noted, such as an erythematous form occurring usually on the forearms, face, and anterior surface of the chest, either diffused or in discrete and irregular spots, or in circumscribed patches.

Rugg (4) reports a case in which, after four grains had been taken every four hours for several days, large red papules, with a shotty feel, came on the wrists and forearms, and from this a uniform erythema, followed by free desquamation, spread all over the body.

The erythematous form may subside in a short time or become intensified and develop into a papular or urticarial form, which may be general over the body, but is more usual on the hypogastrium and extremities; it is said to differ from ordinary urticaria in being brighter—of a rose-red—and of more exaggerated development.

Taylor mentions a case in Charity Hospital in which the urticarial eruption was confined to the face, the neck, and the backs of the hands and wrists; it was always reproduced after a few fifteen-grain doses of the drug, and vesicles usually appeared on the tops of some of the wheals within forty-eight hours.

A purpuric or hæmorrhagic form was first described by Fournier (5), who regarded it as rare, having seen only some fifteen examples. It has also been reported by Vidal (6), T. C. Fox (7), Stephen Mackenzie (8), and others. Mackenzie's case was that of a child who died after two grains and a half had been taken in a single dose. Silcock (9) reports a case in which the purpura disappeared upon the administration of arsenic, to reappear when that remedy was discontinued. In a case of Kuess's, hæmoptysis and metrorrhagia also occurred. Morrow (10) redeveloped the purpura four different times, thus proving its relation to the iodide. It was reproduced within forty-eight hours by five-grain doses of the drug.

Fournier describes this eruption as consisting of discrete, miliary, millet-seed-sized to lentil-sized spots, usually rounded, more rarely oval or discoid in form. Its seats of predilection are the legs, more especially the middle three fifths, avoiding the knees and feet, and it develops more profusely on the anterior than on the posterior surface. As many as a hundred discrete spots may be found on each leg. These purpuric eruptions usually appear in from one to three days after the commencement of the administration of the drug, and rapidly reach their height; if the medicine is discontinued, they disappear in two to three weeks.

A polymorphous form is also encountered, in which the eruption presents at the same time papules, tubercles, and pustules, the papules representing an early stage, the pustules a later one, in the same process. Ecthymatous conditions and furuncles may be evolved from hard papules.

Pellizari (11) has reported a case in which three eruptive forms were present at the same time. There were three slightly elevated papules, of a strawberry-color and slightly rough, on the left forearm near the wrist; on the arms and legs there were several bullæ, half an inch in diameter, surrounded by a circumscribed dark-red areola, and three tu-

mors larger than a nut deeply imbedded in the subcutaneous tissue. All of these elements disappeared rapidly on discontinuing the iodide, the bullæ leaving white scars. The eruption was redeveloped several times by the readministration of the drug, each renewal being accompanied by fever.

G. H. Temple (12) reports a sixty-year-old man with tertiary syphilis who received three times daily a grain (0.6) of iodide of potassium, with the effect that after eight days his hair and beard, normally white, became of a rose-red color. At the same time his linen and the handkerchief with which he wiped off the sweat also were dyed red. On his leaving off the medicament, the abnormal color gradually faded away, but returned on renewal of the drug.

This variety of the iodide eruption which I present was, I think, first described by Fisher (13) in 1859. He states that "a nodulo-pustular form is very rarely observed, and occurs most frequently in scrofulous individuals, usually upon the upper half of the body."

Hutchinson (14) reports a case which he saw of a syphilitic man affected with very severe iodism, with the development of a pustular eruption ending in the patient's death. On the face, arms, legs, and body there were innumerable purple or red, irregular elevations, raised a quarter to half an inch above the level of the skin; semi-fluent, fluctuant, or firm, varying in size from that of a hazel-nut to that of a walnut—one even measured two inches across—some with surfaces entire, others with the summit abraded and discharging a thin, yellowish, offensive stuff. They were both single and conglomerate, and had an inflamed areola.

Tilbury Fox (15) reports two cases; the first, that of a cachectic, feeble syphilitic, who was ordered ten grains of iodide three times daily, which four days later was increased to fifteen grains. The following day there appeared on the forehead, both eyelids, and scattered here and there on the face, scalp, and neck, small vesiculated spots similar to acne. The drug being continued, the following day the acne pimples had become large vesicles filled with a milky fluid, soon changing into thin, inodorous pus. The medicine was stopped, but the eruption increased in size, and some lesions burst, and showed a base covered with florid granulations.

The second case was that of an old woman for whom a mixture was ordered containing among other ingredients a small quantity of arsenic and three fifths of a grain of iodide to each dose. On the twenty-fifth day after she began taking this medicine an eruption of pale, shotty spots was observed over the forehead and the backs of the hands. These lesions increased in extent and intensity, though the medicine was stopped. On the seventh day after the appearance of the eruption bullæ had formed, which on the eighth appeared to be solid and inflamed, and were very painful to the touch. Four days later the eruption had almost entirely disappeared. A week later the medicine was again given, when, after five days, the same papular eruption appeared which developed into large, severe cethymatous elevations containing dark, puriform fluid.

Duhring (16), under the title of Circumscribed Phlegmonous Dermatitis due to Iodide of Potassium, describes a case in which, after the drug had been taken for several weeks, there occurred on the patient's forehead a slightly

inflammatory annular patch, half an inch in diameter, consisting of a number of pin-head-sized vesico-pustular lesions looking like an irritated patch of ringworm. This extended rapidly, and several similar patches occurred elsewhere upon the face. At the end of a fortnight the original lesion was nearly two inches in diameter, and consisted of a circumscribed and defined, irregularly rounded, elevated, firm, inflammatory, violaceous patch. The center was depressed and crusted, while the periphery was studded with numerous deep-seated, yellowish, sebaceous-looking pustules, presenting an acneiform appearance. On raising the central crust, a dark-red, shining, mamillated, or warty surface appeared, and on cutting into the pustules they bled, but did not exude their contents.

Besnier (17) has reported two cases as *acne anthracoidé iodopotassique*, in which the face and thorax were covered with veritable tumors of variable volume, of a reddish, coppery hue, flabby, almost fungous, and presenting punctate depressions or vacuoles analogous to those of anthracoid furuncle. It was impossible to express their contents, and incision gave exit only to blood.

Dr. Taylor (18), under the title *Dermatitis Tuberosa of Iodic Origin*, has reported the case of a syphilitic man in whom the lesions produced by the drug were tumors, deep red in color, of round or oval outline, in size from that of a three-cent piece to that of a quarter-dollar, pedunculated and sessile. The tumors on the side of the forehead and by the side of the nose were pedunculated and mushroom-shaped; the rest of the tumors had sharply defined vertical margins. A thin inflammatory areola was present around each lesion. In structure the tumors were soft, spongy, and non-resistant, the larger ones conveying to the fingers a sensation of bogginess and false fluctuation. On the surface of most of the tumors were a number of minute cribriform openings, from which a small quantity of pus could be made, on pressure, to exude, which, drying, formed crusts of various sizes. Each tumor reached its full development in about a week, after which the openings disappeared; the surface of the tumors now presented a uniform warty appearance. Pigmented patches, decidedly but superficially atrophied, were left. No subjective symptoms beyond a slight pruritic heat were complained of, and there were no systemic disturbances present.

Hallopeau (19) mentions the case of a man, aged forty-eight, who had an eruption on the face and upper extremities consisting of deep-lying scars and vegetations, which had been preceded by bullæ and vesicles. The cicatrices were isolated and depressed, with thin centers, and occasionally covered with crusts and vegetations; they were roundish in outline; in size, from that of a split pea to that of a small coin. A few were elevated above the surface. From the patient's history a diagnosis of syphilis was made, and a gramme of iodide a day was given. After several days there appeared on the backs of the hands blebs with cloudy contents, which dried into a crust; on other portions of the body the same appearances were manifested. After the patient had taken the iodide for fourteen days it was suspended, and after three weeks' time again given, when, on the fourth day, with intense fever, the vesicular formation

again began. A third trial resulted in the same manner. There was therefore no longer any doubt that the eruption was due to the drug, or that the scars and vegetations were the sequelæ of the blebs, which after drying left a scar, and from these scars the vegetations gradually developed.

Hyde (20) has reported two cases also, under the designation of *Dermatitis Tuberosa* due to the Ingestion of Iodine Compounds. The first was that of a girl, aged eighteen, who took, three times daily, teaspoonful doses of a solution containing a grain of iodine and a drachm of iodide of potassium to the ounce. On the third day, attended with moderate coryza, there appeared a number of semi-solid papules on the forehead and two or three on the dorsum of the hands. In the evening of the same day the entire scalp and forehead were covered with small and large lesions of the same general character, rapidly increasing in size.

The drug was continued for nearly a month longer, with constant aggravation of the cutaneous symptoms. Dr. Hyde describes her appearance when he first saw her as follows:

The scalp was completely covered with closely packed pigeon's egg-sized tubercles, the matted hairs projecting through and between them, all smeared with a puriform mucus mixed with the fatty base of the sebum. The forehead, temples, cheeks, neck, and back were generally and symmetrically covered with superficially seated, small egg-sized, semi-solid, discrete and confluent, oval, roundish, and irregularly shaped tubercles, of a dull-reddish hue, some standing out to the extent of several millimetres prominently from the general surface. Their surfaces were usually flattish, occasionally fissured and macerated with a mucoid secretion. Many certainly resembled large-sized secreting condyloma. None were true bullæ, and none when punctured extruded their contents. Some had the appearance of an irregular furrow filled with mucous-pus at the summit, the general line of this furrow corresponding to the axis of the long, oval-shaped lesion, resembling the sausage-link tumors of *mycosis fungoides*. They were evidently masses of softish, vascularized epithelium, secreting superficially a thick, grumous, mucoid fluid, in places commingled with pus.

There were two large, compound nodules on the flexor aspect of the right forearm, two on the left hand, and several on other portions of the body. Iodine was detected chemically in the urine. The patient's general health was excellent. The eruption promptly subsided as soon as the drug was stopped, leaving dull-red infiltrations in patches, covered with light and dark crusts superimposed upon a secreting surface. Here and there slight and superficial atrophy of the skin in patches resulted. After two weeks' time the drug was again administered, with the result of producing the same eruption.

The second case was that of a male infant, seven months old, who, since the age of seven weeks, had been taking a medicine containing, among other ingredients, a grain of iodide of potassium in each dose. When first seen he was covered on the scalp, face, ears, neck, and forehead with an eruption made up of closely packed, confluent, softish, and semi-solid tubercles, of a deep mahogany-red hue, dry and moist in different parts, of about the size of a large pea; roundish or oval in shape, quite commonly flattened

at the apices, often presenting a depression similar to an umbilication, in places smeared with mucus. Some of the lesions suggested in appearance that they had boiled-sago-grain contents; in others, far more numerous, they were simply closely packed, flat-topped, deep-red tubercles of the sort already described, looking very much like mollusca, with semi-solid contents. They were not interspersed with pustules or bullæ, and bore no signs of traumatism.

The pathology of iodide eruptions has been studied by different observers. Thin (21), in examinations of a bullous eruption, found the sebaceous glands unaffected, but the walls of the blood-vessels of a limited area were diseased, permitting the escape of blood, which displaced the connective tissue, pierced the rete, and accumulated under the horny layer of the epidermis. He considers that the injury in its mildest form is seen in acne where limited œdema with congestion of the vessels occurs; and that in severer grades, as in bullous and pustular eruptions, there is an effusion of serum, with more or less of the formed elements of the blood; while in the worst forms, as in iodide purpura, destruction of the walls of vessels and hæmorrhage takes place.

Vincent Harris (22) also reports a case in which he found disease of the blood-vessels, which were numerous, dilated, and sheathed with exudation corpuscles, the effusion being greatest in the papillary layer, which was flattened out. The sebaceous and sweat glands were unaffected.

On the other hand, Adamkiewicz (23) considers the sebaceous glands the starting-point of the eruption, because he has detected iodine in the contents of a pustule; but, as Duckworth (24) records a case of eruption on cicatricial tissue, where probably glands no longer existed, and as eruptions have also been noted on the palms, where normally sebaceous glands do not occur, this theory can not be considered correct.

As to the causation of these eruptions: In a certain number of cases, especially of the severe hæmorrhagic and bullous affections, grave structural changes have been found in some of the internal organs, notably the kidney and heart. This has led to the opinion by some observers that deficient elimination should be held responsible for the skin manifestations. Iodide of potassium is a diuretic by its irritant action on the glandular portion of the kidney, and the iodide can be detected in the urine. Large doses will often produce free diuresis where small ones fail, so that, as has occurred on a number of occasions, an eruption was not produced while patients took large quantities of the salt, but, on their ceasing its ingestion or diminishing the dose, the toxic effect on the skin appeared. But deficient elimination is not present in every case, and that theory will not explain why eruptions have occurred when only a small quantity has been taken, or a small single dose, as in Mackenzie's case. We are therefore compelled to fall back on the term *idiosyncrasy*.

These idiosyncrasies are not manifested by the skin alone, but other tissues may be involved, either in connection with the cutaneous lesions or singly; as, for instance, the congestion, with excessive secretion, of various mucous membranes, which is of more frequent occurrence than skin

rashes, and differs in being more transitory; while an eruption on the skin persists, and usually increases in severity, so long as the drug is continued and even after it has been suspended.

There is perhaps no drug respecting which idiosyncrasy is more common, and the dose required to show this idiosyncrasy so variable. In some only half a grain may be necessary, while other persons may be so tolerant of its effects as to take with impunity over an ounce a day. From this peculiar tolerance and variability in the amount taken, the conclusion can be drawn that it is not the amount of iodide given to patients, but the effects produced, which should be watched, for in some patients a small dose of a few grains daily will achieve more good results than a large quantity given in another case.

Hallopeau (19) has reported a case in which he regarded the idiosyncrasy as having been developed gradually through the long previous use of the drug.

The various cutaneous manifestations of iodide of potassium are supposed to be due to the contained iodine, but that the physiological effects of iodine and iodide of potassium are identical has not been proved. H. C. Wood (25) quotes Kammerer and Professor Binz as asserting that iodides are decomposed in the tissues, and act by liberation of the contained iodine. With these views Wood is not in accord, holding that they have not been proved, and maintaining, further, that the general professional opinion is that iodine and iodide of potassium differ in their therapeutic action. Gaglio (26), from his studies of this subject, concluded that the assertions of Binz were not proved.

Iodide is absorbed, and is eliminated chiefly by the kidneys, and to a greater or less extent by all the mucous membranes and the skin.

Ehlers (27) made seventy quantitative examinations of the urine, and found that an average of eighty-two per cent. of the iodide could be recovered. When symptoms of iodism developed, the urine showed a diminished elimination of the drug, the iodism disappearing as its elimination increased.

Professor Sée (28) asserts that the elimination takes place slowly and intermittently, so that the drug when given continuously accumulates in the system. He further states that it can be found in the saliva after it has disappeared from the urine. The iodine seems to be eliminated partly as an alkaline iodide and partly in organic combination.

It has been further affirmed that the iodide of ammonium stands first in its irritating property and the iodide of potassium next, and that the sodium salt is the least irritating of all. That the large number of cases reported are in connection with the potassium salt is probably due to the fact that this is employed far more frequently than the two others. In Duffey's (29) case iodide of potassium twice developed an eruption; the sodium salt was then employed, in doses of ten grains three times daily for eight days, without producing any eruption. The ammonium salt was then given in two ten-grain doses, and within twelve hours the eruption manifested itself.

Ringer (30) reports a case in which thirty grains a day of the iodide of potassium after five days developed a pustular

eruption; this disappeared in a few days after stopping the drug. The ammonium salt was then tried, but, after the second dose of ten grains, redeveloped the eruption. The iodide of sodium was then substituted in the same doses and continued for four days, but without bringing out the eruption, which, however, promptly reappeared after a single dose of the iodide of ammonium.

Lesser (31) reports a case of erythema nodosum which came on in two days after the internal use of the iodide of potassium. The use of the sodium salt was followed by the eruption in a less severe form. The treatment, after being changed to the subcutaneous use of the potassium salt, was not followed by any eruption.

**Cocaine Fatalities.**—"At a recent meeting of the Société de Chirurgie of Paris, a letter from Professor Germain Sée was read in which he stated that he had collected particulars of two hundred and sixty accidents with hypodermic injections of cocaine, of which twenty-one terminated fatally. The professor considers the drug to be dangerous, and pronounces himself opposed to its employment."—*Druggists' Circular and Chemical Gazette*.

## ASTHMA :

ITS PURELY NERVOUS ORIGIN AND  
AN EFFICIENT TREATMENT.

By B. O. KINNEAR, M. D.

ANY chronic disease which interferes with the entrance of oxygen into the air cells and proves an obstruction to the natural aeration of the blood is a cause not only of distress to the patient from his inability to respire freely, but every function of the body becomes slowly and steadily diseased. This may not be shown for some time in asthma, for the attacks are at first transient, and for a long period the system seems to recover its full vigor between the seizures.

Nevertheless, after a lapse of years, changes in nutrition take place throughout the whole body. Constipation is apt to follow, more or less emphysema results, the heart is weakened, and the right ventricle hypertrophied from the unusual effort required during the spasmodic arrest of normal inspiration.

The digestion is disordered. The nervous system deteriorates. There is more or less constant discharge of mucus from the lungs; the muscular system is enfeebled, and nearly all the processes of nutrition, secretion, and excretion are vitiated. The bronchial mucous membrane is thickened or hypertrophied.

Asthma is one of the most painful and distressing diseases known, yet in itself comparatively rarely proves fatal; yet there is evidently no doubt, from the general impairment of health, that it paves the way for other disorders to invade and assault the already debilitated citadel. These new assailants are noted as the cause of death, whereas had not asthma been present the patient might have recovered. My intent is to present the treatment of asthma and its complications by the use of cold over the spine, as well as to give an explanation of why cold over this region will in many cases restore to full health, and in others repair the diseased condition inducing the spasmodic onslaught, and reinvigorate the whole body to such a degree as to constitute almost a new life; or to revivify the vital powers to such an extent that life becomes once more "worth living," and not a perpetual struggle for breath, as it practically ultimates in a large number of unfavorably progressive cases.

Dr. Alfred L. Loomis, on page 59 of his *Text-book of Practical Medicine*, says: "The spasmodic contractions of the bronchial tubes may be regarded as due to a neurosis, which depends upon the existence of a peculiar diathesis. Some muscular spasm or contraction of the circular muscular fibers of these tubes is the essential element of the asthmatic paroxysm, and the consequent narrowing of the tubes is a necessary mechanical result."

Koss, in his *Diseases of the Nervous System*, page 522, declares: "The symptoms are mainly caused by spasmodic contraction of the muscular tissue of the bronchial tubes.

"The asthmatic paroxysm may be excited by direct irritation of the trunk of the vagus; in other cases it is caused by a reflex irritation of the sensory nerves of the lungs themselves, or of those of remote organs, such as the stomach, the intestines, or uterus.

"An attack sometimes results from central irritation, and it is then generally associated with hysteria."

Flint, in his *Practice of Medicine*, remarks, page 216:

"It is a neuropathic affection, tonic spasm of the bronchial muscular fibers being induced by a morbid excitation through the nervous system.

"The exciting causes of the paroxysms doubtless exert their effect through the excito-motory or reflex function of the nervous system.

"Asthma is always nervous."

He also states on page 218: "Mental emotions sometimes act as an exciting cause of the attacks."

And every physician of middle age is aware that severe shock may give rise to asthma in persons who had previously been quite free from the disease. A noticeable symptom given by nearly all authors as preceding the attacks is a much increased flow of limpid urine, which occurs frequently in nervous people not subject to asthma.

Ranney, in his *Lectures on Nervous Diseases*, page 723, informs us that "spasmodic asthma may be benefited by galvanism of the neck.

"Its beneficial effects are probably due to changes induced in the vagi."

The evidence that this disease is of nervous origin, affecting the circular bronchial muscles, might be greatly multiplied both from authoritative writings and from the records of individual observation; but enough testimony has been adduced to prove that the direct factor giving rise to the asthmatic paroxysms is the narrowing of the smaller bronchial tubes, so that oxygen can not enter the air cells and be absorbed into the circulation, such closure being due to contraction of the muscular fibers around the bronchi.

It therefore clearly appears that if a reasonable hypothesis can be presented demonstrating why these small muscles contract, "by a morbid excitation through the nervous system" the profession will approach nearer than hitherto to a knowledge of the originating cause of asthmatic spasms, and will thus be so much closer to an appropriate and effective treatment.

Gray, in his *Anatomy*, gives us the information that "anterior and posterior branches from the pneumogastric follow all the ramifications of the bronchi." This fact goes to prove that some of the "central cells" of the pneumogastric are the active cause in effecting contraction of these tubes—first, because a nerve separated from its center loses its function; second, when the center is hyperactive, this activity is declared at its terminal end, as illustrated and confirmed constantly by reflex action, and, as the writer believes, from *central* action also, in nervous people, demonstrated in motor nerves by twitching of muscles in various parts of the body, and particularly in chorea. The next question that confronts us is: What condition of these central nervous cells will give rise to contraction of the bronchial tubes? The reply naturally is: An increased activity of the cells, an irritation of them, an overflow of nervous force from them to the bronchial muscles. What can induce this abnormal overflow? What power irritates the cells to so energetic an action, with such distressing

results? It seems to me that the only reasonable and natural explanation lies in the fact of an abnormal circulation of the blood within the group of cells of the pneumogastric issuing nerves to the ramifications of the bronchi.

A condition of dilated blood-vessels, with a hyperactive circulation through the center, would allow of increased nutrition of the cells and a greater impulsion from them than is natural in health; therefore a stimulation of their function, and more forcible nervous currents sped to the muscles about the bronchi, with a resulting contraction and narrowing of the tubes; and, as an outcome, the attack of asthma.

If this hypothesis is true, then any remedy or remedies which will contract the dilated blood-vessels in these centers, either directly or by withdrawal of the excess of blood from them, thus allowing of arterial closure to normal caliber, will most quickly relieve the acute seizure, and, if the blood can be prevented from returning in undue quantity to the center, hinder the recurrence of this painful and distressing disease. That just such an effect may be induced I have now proved in a number of people suffering, many of them for years, from asthma.

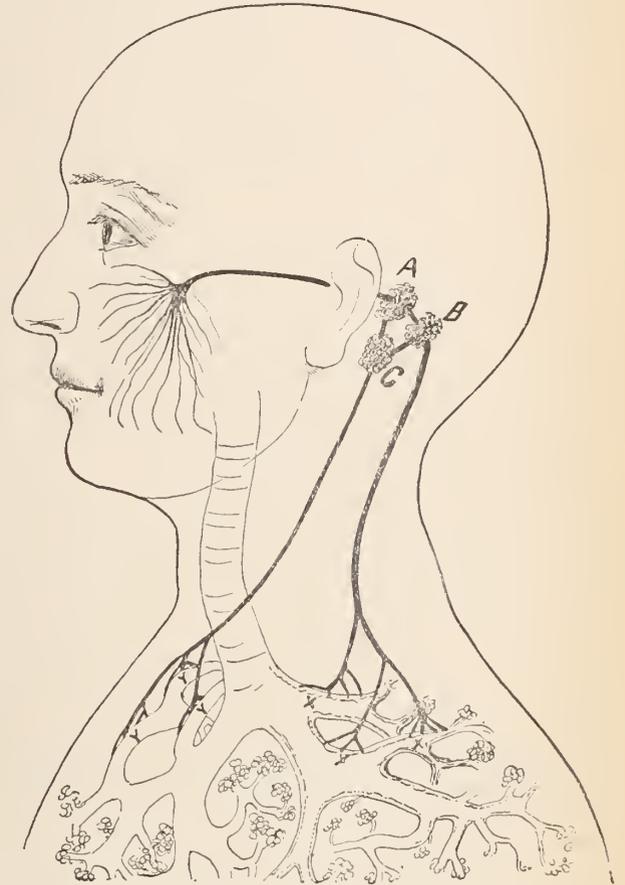

My own belief is that there are two varieties of nerve involved in the production of the disease. They are the motor, already spoken of, and the accompanying trophic or nutritive nerve, which latter terminates in the cells of the lungs and the cells of the bronchial mucous membrane. It is now very generally recognized that every motor nerve has a second function—viz., that of regulating nutrition to all cells in the area over which the motor is distributed, so that nothing new is advanced by this statement; but a satisfactory explanation is thereby added to the pathological effects produced upon the bronchial mucous membrane in many cases. The effect here referred to is the congestion and thickening of that membrane in many chronic cases, this very turgescence adding a further obstruction to the entrance of air into the air cells; as well as from the hyperæsthesia of the mucous membrane induced, causing, when irritated by smoke, dust, ipecac, odors of various kinds, sudden colds, etc., a reflex spasm of the tubes through the sensory nerves. These trophic nerves appear, therefore, to arise in the same group of pneumogastric cells as the motor. The accompanying cut, used in my article read before the Hay Fever Association, in Bethlehem, N. H., in 1890, and produced in their report of 1890 as one of four illustrations of the nervous centers involved in that disease, demonstrates very clearly the hypothesis advanced. The centre, B, shows a group of pneumogastric cells distributing nerves to the bronchial mucous membrane, X, X, X, X, causing, when the center is hyperæmic, tumidity of the mucous membrane of the tubes.

The central group of cells, C, the nerves of which terminate on the muscular striæ surrounding the tubes Y, Y, Y, when hyperæmic, gives rise to contraction of the muscles and the closure of the tubes.

The expansions, O, represent the air cells.

By excluding, then, the excess of blood from these respective centers, their function is brought to the normal; consequently the muscles about the bronchi expand, and the swelling of the mucous membrane subsides.

This result is attained by ice applied over the spine in such a way that, the circulation being naturally distributed over the body, the congestion of the centers is at once lessened in the acute attack; and, by an expert application of the same remedy, used for weeks in some cases and for a much longer time in others, the blood is kept away in excess from the centers, the weakened coats of the arterioles within them recover their normal, or almost normal, contractility, and either great relief or a cure is obtained.

But this is not all the good which may be assured by the use of this remedy.

If there are cold extremities, as is frequently the case in asthmatics, they are warmed and strengthened also by the increased nutrition due to a larger supply of blood.

If there is indigestion, the condition may be much benefited through a more active circulation induced in the gastric glands, the pancreas, and liver, resulting in a larger supply of digestive fluids. The secretions throughout the intestines are increased for the same reason, and peristaltic action renewed by reinvigoration of the muscles around the intestines, and constipation relieved, if present, to a great extent, in some cases wholly. These results are due to the fact, proved now by hundreds of cases, that ice over the spine dilates the arteries throughout the body, distributing the blood to organs and tissues where there has been an insufficient supply.

The excessive secretion from the bronchial tubes, a very distressing factor in chronic forms of the disease, is largely diminished also by ice over the spine.

By the relief to the contraction of the tubes and the subsidence of tumidity of the bronchial mucous membrane, the hypersensibility of the whole tract is lessened, so that reflex spasms are much less liable to take place.

Reflex spasms also, from indigestion and impacted rectum, disappear as well by the relief given to these conditions.

It is most astonishing and delightful to witness the change from deficient to healthy action in various organs, as well as a return to normal nutrition and strength throughout the whole body, under the expert use of cold over the spinal nervous centers, due in large measure to the distribution of a sufficient circulation to parts of the economy where it has been less than normal, and, oppositely, the abstraction of blood from other portions of the same where circulation has been excessive.

Many people who have lost weight rapidly regain it, and stouter persons lose flabbiness and become solid to the touch, with a great addition to the physical strength. While the writer is convinced of the truth of the hypothesis set forth, he does not expect to convince his medical *confrères* of the same by an essay, yet, from the results obtained in the following cases, he hopes to induce those who have time for study to investigate Dr. Chapman's system for themselves in reference to the treatment of asthma, and, in fact, in reference to the general treatment of disease, which the author of this paper has found of immense service to himself, as well as to patients suffering from a variety of complaints.

I hold, with Dr. Chapman, that the health of the body is regulated and controlled by the combined normal action of five sets of nerves—viz., the sensory, the motor, the trophic, the sympathetic or vaso-motor, and the nervous supply to glandular organs, which latter may be accounted as a division of trophic nerves, as they have to do with secretion and excretion.

And, finally, that a limited or excessive amount of blood circulating within their centers constitutes not only disease in the centers, but through that abnormal condition disease is invariably demonstrated at the termination of their nerves. The application of ice over the spine is always soothing and agreeable when necessary, but particularly to those people who are always chilly and nervous. It relieves the surcharged nervous centers of their blood in such cases, and warms and nourishes the whole body.

CASE I.—Mrs. —, of Boston, Mass., sixty years of age; treated in 1882. She had been a sufferer from asthma for sixteen years, the disease increasing in intensity year by year until at the time of examination she was confined to her bed three or four days out of each week, with dreadful distress during the whole attack. She had become emaciated to such a degree that the husband of the patient remarked to me: "Doctor, my wife is but a bag of bones now, and you will freeze her to death by applying ice over her spine." He, however, decided to try the remedy. The appetite was very poor, and she suffered greatly from indigestion. The whole body was cold to the touch, but the legs and arms especially so. The pulse was rapid and weak, the bowels were constipated, and the patient was exceedingly nervous. Ice was applied in a full-length bag, extending from the fourth cervical to the third lumbar vertebra, and used four

hours a day, an hour at a time. The patient was wheezing at the time of the first application, which discomfort was relieved during the first hour, and the patient's nerves were much soothed as well.

The progress upward was most rapid and well pronounced from the outset of treatment. Some attention was given to the digestion, and a few laxative eholagogue pills were used during the first few weeks. Her appetite speedily improved, and she gained very fast in weight. The body and extremities became permanently warm. The general physical weakness disappeared wholly. Natural action of the bowels gradually recurred. The pulse beat much more strongly and regularly. The general nervous hyperæsthesia departed and the paroxysms of asthma grew less violent and frequent, while their duration was shortened to scarcely an hour at a time after three months' treatment. She used to say: "Doctor, directly I find the attack coming on I apply the ice and it is at once checked, passing rapidly away." This patient was practically well in six weeks, and during the rest of her life remained almost wholly free from the disease and its distressing results. She died some four years afterward from another disease.

I should consider that the emaciation, weakness, dyspepsia, constipation, etc., relieved also by the treatment, had been wholly caused in this patient by the severe and protracted asthmatic paroxysms, interrupting free oxygenation of the blood, therefore vitiating its quality and so hindering normal nutrition throughout the body. Secretion and excretion could not be sustained naturally. This result illustrates the rapid benefit which is obtained by the treatment in a case of uncomplicated asthma in a person of originally strong constitution.

CASE II is that of a boy of about twelve years of age, treated in the Catskills during August of 1885. He was the son of the man in charge of a New York fishing club, and inherited the disease from his father, a man of about forty-five years of age. The father had been afflicted with asthma since early boyhood, and was of an exceedingly nervous temperament. The boy seemed well and full of life and spirits, but suffered with nocturnal attacks frequently for several successive nights, lasting from about midnight until daylight. He used a ten-inch ice-bag between the shoulders, from about the first dorsal vertebra downward, twice a day and for three quarters of an hour at a time for a few days. Afterward once a day was found sufficient to check the attacks and lengthen the periods between them. He used the bag by my advice for several months. I heard of him again in 1887 as quite well. When the bag was applied the first time his attack was relieved and he was sound asleep in fifteen minutes. This case is particularly interesting as being one of hereditary asthma.

CASE III.—Mrs. D., sixty-six years of age, living in Boston, had been troubled with asthma for many years, particularly in damp weather. For several years has had chronic bronchitis. The heart is weak, the digestion poor, the circulation feeble, and there is a tendency to constipation. A son of hers, a physician, died of consumption. He was a very large man, and until attacked looked the picture of health. This patient was much benefited by the use of ice over the spine from the second dorsal to the third lumbar vertebra. The spasmodic seizures were much relieved in duration, frequency, and intensity. The large amount of watery mucus usually coughed up daily greatly lessened and the appetite and general strength improved. She used the treatment for more than a year under my care, at times remaining quite free from the disease for weeks together, a most unusual experience; but she had to use the bag steadily

three or four times a week to retain the improvement. She then removed to Concord, N. H., since which date I have heard nothing from her. The results achieved appear to the writer satisfactory when her age is considered.

CASE IV is that of a shop girl, naturally delicate, and overworked during the two preceding years. She had a large number of fainting spells, a weak heart, a poor digestion, was exceedingly nervous, and was troubled with constipation and dysmenorrhœa. She also had frequent headaches. The treatment had to be used with great care in this case, as the patient was so thoroughly exhausted, and it was necessary to her support that her work should be continued. The use of the ice was combined with tonics and laxatives, and she gradually improved in all respects, and at the termination of eighteen months was as well as she probably ever could be. The asthma had quite gone; her nervous condition was much improved. The bowels only needed occasional assistance. Menstruation was normal, her circulation was good, and she was enabled to perform her daily work without great fatigue. Her headaches were less frequent and her sleep refreshing.

CASE V was that of the brother of an old professional friend. He was forty-three years old. Had suffered from asthma many years. When examined he was in a pitiable condition. He had not been free from the asthma for three months, was greatly emaciated, and had a constant cough night and day, which would continue hour after hour, and had almost completely prostrated him. He was suffering from night sweats, with some slight rise of temperature. There was no consolidation of the apex of either lung. There was a good deal of frothy and mucous expectoration. His appetite was capricious and small. His bowels were constipated, and his legs, arms, feet, and hands cold. The whole external surface of the body had a bluish tinge. Ice was used night and morning for an hour and a half over the last eight dorsal and first three lumbar vertebrae. In three weeks' time he recovered almost full strength, with a great increase of weight, a good appetite, and the only trace of asthma left was a slight wheezing on over-exertion. Against my own judgment he persuaded me to let him take a journey and do some important business requiring fatiguing exertion. Almost immediately after his return he was attacked most violently with all his former symptoms, and rapidly retrograded to his former condition. The treatment was carefully continued for some time, but without good effect. I discontinued the use of the bag, feeling that his vitality was at too low an ebb to afford him benefit. He died some months afterward.

My impression is that, could the patient have continued to rest after making his remarkable gain for some months, he might have fully recovered; but, having a wife and children dependent upon him, he felt that as soon as he had gained he must use his strength, and in consequence relapsed.

There is no doubt that a fruitful source of the spasmodic seizures of asthma is bodily exertion, and an uneasy mental condition another.

CASE VI.—Mr. F. G. L., fifty years old, examined in July, 1888. Has had asthma for forty-four years. The disease has increased in violence, particularly during the past two years. Has not now been free from asthmatic breathing for six months. There are frequent and exceedingly violent nocturnal spasms of the disease. The only relief to be obtained of late at these times has been given by injections of morphine, one third of a grain, atropine, one one-hundredth of a grain, often twice in the night. The patient is learning to depend on opium for relief. He suffers with great mental depression. The apex of the head espe-

cially is abnormally hot. The digestion is not so good as formerly. The bowels constantly tend to a more severe constipation. The legs and feet are a good deal cooler than the upper body, but very much colder during the nocturnal attacks. For two months at Bar Harbor this gentleman required constant attention. The first improvement noted was a better circulation in the lower body, while the ice-bag, when applied over the dorso-lumbar region, soothed the patient, frequently checked the attacks, and enabled him to do without morphine. His appetite and digestion began to improve. The head became much cooler and the spirits improved. After his return to Boston the general strength increased, and during the past two years he has never had to resort to morphine. The spasmodic attacks have been infrequent and much less violent. He has continued the treatment at intervals, and while he will probably never fully recover from the disease, he is much stronger than for several years previous to treatment, unless he be subject to great and long-continued bodily fatigue, mental strain, or exposure to cold or damp.

I believe not only that the attacks may be held in abeyance, but that they will lessen in number and severity with increasing age. The arterioles in the pneumogastric center will never probably, after forty-four years' dilatation, contract to the normal; but, by a sufficient use of the treatment to keep the circulation throughout the body properly distributed, thereby both withdrawing excess of blood from the centers as well as nourishing and strengthening the whole physical framework, comparative freedom from the nocturnal attacks may be assured, and a state of health secured. In one of my cases of hay fever treated during the season of 1891 the asthma concurrent with the nasal trouble in this patient was wholly relieved.

46 WEST SEVENTEENTH STREET, NEW YORK.

## THE NATURE OF INFLAMMATIONS IN THE LIGHT OF RECENT DISCOVERIES.

By W. P. CARR, M. D.,

PROFESSOR OF VISCERAL ANATOMY AND DEMONSTRATOR OF ANATOMY  
IN THE MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY, WASHINGTON, D. C.

So much of the mystery connected with this subject has been cleared away by the investigation of recent observers that we are now in a position to drop much of the old mysterious technology in regard to inflammation and to explain its varieties and phenomena as clearly and rationally as we can explain any biological process.

Before beginning to discuss the subject in a connected manner, I will make the following propositions, which I consider either as axioms or as propositions proved, and acknowledged as proved, by the majority of the profession.

I. All inflammations are, strictly speaking, local, as we know of no disease in which all the tissues of the body are inflamed. Even if specific fevers be regarded as inflammation, or fermentation, of the blood, having in addition in many instances lesions of solid organs or tissues, we must remember that the blood is only one of the many tissues of the body, and hæmatitis is as much a local affection as peritonitis.

II. The effects of local inflammations may become general in at least three ways. First, by the action upon the

nervous system of septic poisons absorbed into the blood. Secondly, by direct injury or irritation to the nerves in the inflamed area, causing shock, pain, loss of sleep, and reflex disturbances of the general nervous system. Thirdly, through the drain of suppuration.

III. Every cell in the body is directly or indirectly under control, more or less complete, of the nervous system. This includes the blood cells, which are controlled indirectly by the vaso-motor nerves.

IV. The following phenomena of acute inflammation have been actually observed—viz., a dilatation of the capillaries of the part, a slowing of the current, accumulation of leucocytes around the periphery of the vessels, complete occlusion of the vessels in places by the leucocytes, stasis, clearing of the lumen of the vessels by the passage into the tissues of these aggregated cells, escape of plasma into the tissues, transformation of escaped cells into connective-tissue cells, and, in septic inflammations, the presence of bacteria in the interior of escaped white blood-cells, sometimes showing evidence of degeneration or digestion by the cell.

V. The escape of leucocytes from the blood-vessels and their transformation into connective tissue also take place normally and in normal tissues.

VI. The escape of plasma also takes place normally for the purpose of bathing and nourishing the cells of the body, and is returned to the blood-vessels by means of the lymphatic circulation.

VII. The plasma that escapes in inflammation serves as a culture medium for the escaped round cells, and exerts a germicidal action upon bacteria.

VIII. This escape of blood elements, which is the essential feature of inflammation, is therefore only an exaggeration of a normal process.

IX. Aseptic inflammation can be caused only by destruction or irritation of tissue by mechanical or chemical means, or by heat, cold, or electricity, under conditions that prevent the access of bacteria. But any aseptic inflammation may quickly become septic by access of germs to the tissues.

X. Aseptic inflammation is only a process of repair, and consists essentially of a replacing of destroyed tissue by connective tissue formed from the colorless blood-cells. Aseptic inflammation of a low degree may be indefinitely prolonged by the circulation in the blood of some toxic substance, purely chemical, which continues by its presence to irritate or destroy tissue. Otherwise, aseptic inflammations either become septic or result in repair, or what we term resolution. This repair may be delayed by lowered vitality of the tissues, and in case of bone injury by lack of bone-forming material in the blood plasma.

If we consider these propositions proved, as I think we must, then we may give a more definite explanation of aseptic inflammation than has yet been done.

Take, for instance, a contusion with subcutaneous laceration of tissue. The injured afferent nerves carry an impulse to the vaso-motor centers (we need not now consider where these are situated), and through the vaso-motor nerves the capillaries are dilated. This dilatation causes a

slowing of the blood current, and either opens pre-existing stomata in the capillary walls, or causes a relaxation and separation of the single layer of cells forming these walls, so that plasma begins to flow out through these openings. Many of the openings become choked by the colorless corpuscles that come lazily floating in the periphery of the slow blood-current and are swept into the openings or stomata by the outgoing plasma. Other leucocytes catch against these, and the vessel becomes entirely occluded in places. Stasis results. But the cells finally pass out by amoeboid movement or are forced out by the blood pressure, the lumen of the vessel is re-established, and the current begins again. The cells after their escape wander about for a time by their inherent power of amoeboid movement, nourished by the plasma that accompanies them, and which continues to pass out of the vessels and be absorbed by the lymphatics; but, finally, they become fixed, shoot out processes, and are thus transformed into connective tissue. It is possible that these cells may proliferate after their escape, and that there may also be proliferation of the older connective-tissue cells, but I regard this as improbable. The new connective tissue is laid down around capillary loops that shoot out from the blood-vessels just as they have been seen to do in the developing chick, and thus the destroyed tissue is replaced. Such cells as were killed in the original injury break down and form a mass of *débris* that is carried off by the lymphatics or absorbed by leucocytes as food. This *débris* has been called pus; but it is not what we commonly understand by pus, and should not be so called. The amount can not exceed the amount of tissue originally killed, and if the tissues remain aseptic, it is always completely absorbed. Not only so; this absorption must precede the connective-tissue formation, and the amount of new connective tissue usually corresponds to the amount of tissue destroyed. Sometimes, however, when there is more irritation of nerve terminals than destruction of tissue, the new connective-tissue formation may be excessive. Particularly is this the case when the nerve irritation is increased by some form of chemical toxæmia, intestinal toxæmia, lithiasis, etc.

Aseptic inflammation, however, almost invariably terminates in rapid resolution, and leaves little trace behind. But any inflammation may become septic. And undoubtedly in open wounds this result is usually brought about by contact with some substance containing germs upon its surface. Rarely germs are deposited in the wound from the air or from particles of dust floating in the air. Still more rarely, we must believe, with all the evidence before us, true auto-infection takes place from germs floating in the blood of the individual. We can readily understand how this occurs in those diseases where pathogenic organisms are in the circulation, and it is more than probable that even in the blood of apparently healthy individuals some of the milder kinds of pathogenic germs may occasionally be found. Such germs are not vigorous and are not able to harm active cells, but, when brought in contact with injured cells and dead *débris*, may multiply, become vigorous, and cause serious results. They may cause suppuration, or may seriously interfere with the healing of the wound without

causing suppuration, especially if the tissues are already weakened by malnutrition or toxæmia. Pyogenic bacteria may also gain access to subcutaneous lesions through microscopic abrasions of the cuticle, or, as recently pointed out by Dr. Welch, of Baltimore, from the deeper layers of the epiderm itself. Dr. Welch, in a paper read before the Congress of American Physicians and Surgeons, recently announced the discovery of a germ, very much like the *Staphylococcus pyogenes albus*, almost invariably present in the deeper layers of the epiderm, not amenable to washing or superficial disinfection, and capable of producing pus under favorable conditions. He regards it as the usual cause of stitch abscess. He has also made the following interesting observations: Healing by first intention is not proof that no organisms were present, as he has found germs in the serum from such wounds. They were never abundant, however, nor of a virulent kind. He also finds that the power of a germ depends largely upon the amount of poison it carries with it, and that if germs are freed from the culture medium, rich in poison, in which they have been developing, they are much less active. He also finds the blood serum to have antiseptic properties, and that some tissues are much more resisting to germs than others in the same animal.

Thus the peritonæum was able to dispose of twenty times as much of a certain culture fluid, containing pyogenic bacteria, as was required to cause suppuration in the eye of the same animal.

We must conclude, therefore, that the tissues of the body are able to kill and dispose of a certain variable number of most kinds of bacteria, and that this power is modified by at least six factors—viz.:

1. The kind of tissue.
2. The condition of the tissue as to vigor of its cells and antiseptic properties of its blood plasma.
3. The kind of germ.
4. The number of germs.
5. The condition of the germ, both as to vigor in multiplying and producing poison, and as to whether or not it is accompanied by a quantity of its poison, and thus armed and enabled to destroy at once a number of cells in its immediate vicinity, and thus gain time for reproduction.

Therefore, when germs gain access to an area of inflammation, we are confronted by a very complex problem.

If a limited number of germs be present, if they are not too vigorous in producing poison, and if this poison is not of too virulent a kind, they are eaten by the white blood-cells that come pouring from the vessels, or are killed by the blood serum, and find their way into the leucocytes by chemotaxis; and the result is the same whether we call it phagocytosis or chemotaxis. The germs are destroyed and resolution and repair take place, as in aseptic inflammations.

But in other cases the germs are too powerful. They kill the cells by the excretion of poison, and this may take place after the germ has got inside the cell. Should this state of affairs occur in the deeper tissues, those cells in the center of the inflamed area are killed, and can not, of course, form connective tissue; but those around the periphery make their usual change into connective tissue, and thus wall up the pus and germs, forming an abscess. Here,

shut up with their own excretions, the germs may, after a longer or shorter time, die, and the fluid in the sac become absorbed, leaving a cheesy mass that may remain indefinitely. More or less of the poison, however, passes by osmosis or is forced by pressure through the abscess wall, is absorbed into the lymphatics, poured into the blood, and gives rise to systemic symptoms by its action on the nerve centers.

In other cases the inner layers of the sac are killed by the virulence of the poison, and form fresh pabulum for the imprisoned germs, while fresh layers of cells are continually deposited on the outside. Thus the abscess grows until some surface is reached upon which it may burst.

In such cases as this we have practically an aseptic inflammation, around and outside the abscess wall, caused and maintained by the chemical poison transuded or forced through the wall from the active poison factory within, while the wall checks the movements of the germs and prevents a general and rapid spread of the inflammation.

After the abscess breaks, if not into some cavity, the larger portion of the germs and the poison are extruded and usually the cavity soon closes, largely by contraction of its walls, partly by formation of connective tissue, which is now produced more rapidly than it is destroyed. But should the abscess break into a cavity, such as the peritonæum, the germs, finding themselves in new pabulum, and already armed with a large amount of poison, increase rapidly and overwhelm the system by the rapid production of their deadly excretion. Unless this is promptly removed, there is but the faint hope for the patient that the germ may succumb to the combined action of its own poison and the antiseptic serum, before the organism attacked.

That this fortunate termination may ensue is probable, in some instances, when even the peritonæum is invaded by pyogenic organisms. It must be due to the fact that the germ, when weakened by the antiseptic serum, is even more susceptible to its own poison than the patient; that recovery takes place from typhoid fever and other specific diseases. Otherwise the germs would continue to increase *ad infinitum*, or, at least, until the death of the patient. It is well known that many germs are readily killed by their own excretions. Those that produce lactic acid are readily killed by lactic acid; those that produce substances like carbolic acid are readily killed by carbolic acid.

But we may have a form of septic inflammation where the germs are so active and where their poison is so violent that the cells are killed too quickly, and the inflammation extends too rapidly, for any limiting wall to be formed. Such inflammation is produced by the erysipelas germ when once it has become lodged under the skin in the cellular tissue. Here, again, our only hope is that the germ may succumb first to the combined power of its own poison and the antiseptic action of the lymph or that it may at least become so enfeebled as to die without leaving progeny.

Diffuse suppuration may also be produced by slow and comparatively mild germs when the tissues of the body are much enfeebled by malnutrition, hæmorrhage, shock, etc., or by the action of a poison—such, for instance, as the ab-

sorption of ptomaines from the intestine. Here the inflammation fails to be limited because the cells of the body are too feeble to act promptly, and, perhaps, because the blood plasma has lost its antiseptic properties.

On the surface of a tissue, or in open wounds, the process is modified by the fact that the germs and their poison are free to flow away from the body with the pus, and, as there is no pressure, there is little absorption of poison. Hence it takes a large area of superficial inflammation to produce systemic symptoms, and, as the absorption is slight, the destruction of cells is less active than the process of repair. Consequently, unless we have to deal with germs of unusual virulence, such as those that produce hospital gangrene; or, unless the tissues of the body are so feeble as to allow of phagedenic ulceration, the destroyed tissue is entirely replaced by connective tissue, and we have what we call healing by second intention. In those exceptional cases, however, the destruction will continue to spread until the germs are destroyed by caustics or other means.

Thus we see that every form of acute inflammation is a conservative process; and not only so, that it is only an excessive activity or exaggeration of the normal functions of living tissue.

We see that it consists essentially in all cases of a warfare of the blood elements upon bacteria and a replacing of destroyed tissue by round cells from the blood. Why, then, may we not define inflammation as *an unusual activity and concentration of blood elements in a tissue for the purpose of repairing injury or repelling noxa?*

And this definition need not be limited to acute inflammations. For, although there is some difference of opinion about chronic inflammations, particularly the scleroses, as to whether connective tissue is formed first, or whether destruction of cells takes place first, we must regard them as conservative. We must admit that they consist in a formation of connective tissue or glia, either for the purpose of replacing destroyed cells or for the purpose of walling out and limiting the action of a poison or irritant, a noxious substance.

Understanding thus the nature of inflammation, and being able to explain all its varieties, we are surely in a better position to prevent the dangerous forms—to prevent, in fact, all forms except the aseptic, and to guard against the danger of auto-infection and of operating upon tissue enfeebled by the absorption of ptomaines from the intestine.

### HYGIENIC CLOTHING.\*

By FRANK H. DANIELS, A. M., M. D.,  
VISITING PHYSICIAN TO THE MANHATTAN HOSPITAL.

At the present day scientific clothing enters so largely into the modern economy that it is important for us medical men to look back occasionally and review the progress which has been made in this department. Not as tailors, to be sure, for with the æsthetic side of this question I will

not weary you. But as hygienists it is necessary for us not only to be abreast of the times, but also to understand thoroughly what is required of good clothing, and how that requirement can best be filled. The outer clothing may indeed adorn; the inner must be made on scientific principles, and the latter is of the greatest importance.

An ideal clothing is one which does not interfere with the functional activity of the skin, while it at the same time protects it against sudden changes of temperature. The normal skin is an excretory as well as a secretory organ, excreting a small quantity of salts, a little carbonic acid, and a large quantity of water in the form of perspiration, both sensible and insensible. The total amount excreted by the skin is, as you know, large, and has been estimated by Sequin as eleven grains in a minute, or more than two pounds in the twenty-four hours.

The quantity of carbonic acid thrown off by the skin of a healthy man in twenty-four hours is about one hundred and fifty grains; this quantity is, however, increased by a rise of temperature or by exercise. The quantity of oxygen consumed is about the same; but the thickness of the human epidermis affords a great obstruction to any diffusion between the gases in the blood of the cutaneous capillaries and the external air.

According to Foster, the proportion of the insensible to the sensible perspiration will depend on the rapidity of the secretion in reference to the dryness, temperature, and amount of movement of the surrounding atmosphere. Thus, supposing the rate of secretion to remain constant, the drier and hotter the air, and the more rapidly the strata of air in contact with the body are renewed, the greater is the amount of sensible perspiration which is by evaporation converted into the insensible condition; and, conversely, when the air is cool, moist, and stagnant, a large amount of the total perspiration may remain on the skin as sensible sweat.

This excretory activity, or, as we shall call it, the functional activity of the skin, is usually dependent upon vascular dilatation. When the excretions of the skin are diminished, the cutaneous blood-vessels are usually found contracted; and *vice versa*, when these vessels are dilated, the excretions become increased in quantity. And by this contraction and dilatation of the cutaneous blood-vessels, with the accompanying variation in the quantity of perspiration, the temperature of the body is largely regulated. It is found that the excretory organs of the human body will do each other's work to a certain extent, and that, if the skin is not acting normally, its excretions are taken care of by the other excretory organs—viz., lungs, kidneys, and bowels. The balance of health is, however, under these circumstances, disturbed, and such vicarious action will not be long tolerated.

It will be seen from the above how important is a normal cutaneous function, and how far-reaching is any disturbance of its proper activity. It may be stated as facts, firstly, that, excluding contagious diseases, all acute forms of disease may be avoided if the skin is acting properly; secondly, all chronic diseases may be held in check by keeping up the functional activity of the skin. Whenever

\* Read before the Harvard Medical Society of New York City, January 9, 1892.

a patient, suffering from chronic disease of any internal organ, seeks our advice, we always do everything in our power to keep the skin in an active condition; and we find that, when the latter gives out, our treatment is of little avail.

The function of the skin being threefold (an excretor of gases, an excretor of fluids, and a heat regulator), a perfect clothing must answer a threefold requirement, and we will now investigate the properties of fabrics in general use with regard to their porosity, hygroscopic qualities, and heat-conducting qualities.

Linen, silk, cotton, and wool are the only materials we shall consider, as they are the only ones which are now, or ever have been, used to any extent in clothing.

No kind of clothing fabric yields warmth; it can only preserve the natural warmth of the body, and prevent its radiation or conduction, and this it does well or badly according as it is a bad or good conductor of heat.

Count Rumford was the first to experiment in this direction, and he proceeded as follows: Several thermometers with long stems were wound about with a certain weight of the different materials to be tested, and, after being plunged into boiling water, and allowed to cool to a certain point, were then placed in a freezing mixture. The time required for the different thermometers to reach certain points was then noted, and in this way he was able to determine which material protected the bulb of the thermometer best from the surrounding medium, or, in other words, which was the best non-conductor of heat.

These experiments show that raw silk, as spun by the worm, is the best non-conductor, and that raw wool is the next best, followed by silk thread, spun wool, cotton, and linen. Raw silk can not be used, so that wool stands at the head of our list, and raw wool stands to spun wool as a non-conductor as eleven to nine—*i. e.*, it is over twenty per cent. better.

Parkes's experiments have shown that the hygroscopic properties of wool, as compared with cotton or linen (and these two stand about the same in this respect), are twice as great when weight is compared with weight, and four times as great when surfaces are compared. Perfectly dry wool can absorb fifty per cent. by weight of water, and retain from twelve to eighteen per cent.

The function of perspiration, as well as of heat regulation, takes place best when the fabric next the skin is a thoroughly porous one; and Pettenkofer's experiments have shown that, if heavy flannel be taken as allowing one hundred parts of air to pass through, linen will allow sixty and silk only fourteen parts to pass through.

The *Medical Record* for January 15, 1887, said: "There is no doubt that wool stands at the head of the materials out of which clothing is made. Its virtues depend upon its being a poor conductor of heat, its porosity allowing the passage of the exhalations from the skin, its power of absorbing moisture, and giving it up slowly and gradually."

Nearly a century ago Count Rumford said that woollen clothes greatly promoted insensible perspiration, owing to the strong attraction which subsisted between wool and watery vapor which was continually issuing from the human body. "It is evidently not due to the warmth of the covering; for

the same degree of warmth produced by more clothing of a different kind does not produce the same effect. It is a mistaken notion that it is too warm a clothing for summer. I have worn it in the hottest climates, and in all seasons of the year, and never found the least inconvenience from it. It is the warm bath of a perspiration confined by a linen shirt, wet with sweat, which renders the summer heats of tropical climates so insupportable; but flannel promotes perspiration, and favors its evaporation; and evaporation, as is well known, produces positive cold."

It will be seen from what has already been said that wool answers each one of the requirements of a perfect clothing material in the highest degree; and it only remains for us to determine how wool shall be used so as to take the greatest advantage of its properties. Until recently the only woollen fabric we have been acquainted with practically has been flannel, where the wool is first spun and then woven more or less tightly into a fabric. By this means the value of all the properties which make wool pre-eminent as a clothing fabric is diminished; and laboratory experiments made with wool as it comes from the sheep do not agree with those made on flannel—*i. e.*, spun and woven wool. In order to preserve the absorptive property of wool in the highest degree, the fibers must be arranged with their points against the skin, and not longitudinally, as in a woven fabric. This idea has already been recognized and taken advantage of by the originator of the Jaros hygienic underwear, and I pass around for your inspection a few garments made from this material. It is, as you will see, unspun wool caught into the mesh of a loosely knitted cotton back in such a manner as to preserve unimpaired all the properties which make wool valuable as a clothing fabric. Let me briefly recapitulate the qualities demanded of a clothing fabric, and then tell me if this fabric does not answer these requirements in the most admirable manner. It should be hygroscopic, porous, and so loosely woven as to include more or less air in its meshes. For, as has been pointed out above, less heat is lost by radiation if the body is surrounded by a layer of air heated to the body temperature or thereabout. Krieger has already called our attention to the fact that the outer framework of a fabric is but secondary in importance of action as a covering or clothing material when the material next the body has the important qualities just mentioned as being possessed by the Jaros hygienic underwear. I have here a sample of the latest production of the Jaros Company, which may be said to be the most perfect clothing fabric made. The framework or back of this is silk, rendering the fabric still lighter. The arrangement of the wool is such that, by capillary attraction, perspiration is absorbed, and carried to the silk or cotton back, whence it is evaporated into the surrounding atmosphere; and this attraction is so great that the back may be thoroughly saturated, while the wool next the skin is perfectly dry. When our clothing is damp from perspiration, or from any other cause, our bodies lose just as much heat as the moisture in the clothing is capable of absorbing. The importance of always having dry material next to our skin is evident; and the material which will retain the least moisture is the best. Woolen fiber is found

to answer this purpose more nearly than any other. The Jaros material is highly porous, allowing free ventilation; at the same time a large amount of air can be caught, and rendered to a certain extent immovable, thus preventing too rapid loss of heat by radiation. Von Ziemssen, in vol. xviii of his *Encyclopaedia*, says: "A material of loose texture confining much air in its interstices is warmer than the same amount of clothing material closely woven. Wool or cotton carded and spread out in the shape of a wadding and held will make a warmer garment than the same quantity spun and woven and similarly covered. This applies with force to underclothing." This fabric does not shrink; for cotton, the material of which the framework is made, never does to any extent.

While citing perfection attained in clothing materials, we are confronted by the Jaeger material, or stockinet, a loosely-knitted flannel made of pure wool, and comparing most favorably with the pure knitted woolen garments of the old established and renowned manufacturers, Cartwright & Warner, of England. Carefully selected wool is, no doubt, the great claim for this fabric, which is well as far as it goes. In the Jaros material, on the contrary, we find a practical accomplishment of scientific theories, the caprice of no one scientist having been followed out, and, in contradistinction to "systems," in which the professional world finds nothing new, we have a simple, practical, scientific material.

It is only recently that I have had my attention drawn to this Jaros wear, and have had an opportunity of testing it; and I must confess that nothing has given me such personal satisfaction and comfort. I have gone out into the cold from a small, overheated tenement-house room after performing a difficult and tedious obstetrical operation, with my white shirt saturated with perspiration, and have felt no trace of chill. And I have found on reaching home that, although my white shirt and the cotton back of my Jaros wear were wet, the wool next the skin was perfectly dry, as well as the skin itself. And this winter, for the first time in years, I have had no nasal catarrh, from which I usually suffer every autumn and winter; and I attribute my escape so far solely to my Jaros underwear. And, in this connection, let me say that Dr. O. B. Douglas, in a discussion before the Post-graduate Clinical Society, on the treatment of nose and throat diseases, expressed himself equally pleased with this wear.

Underwear of this description is of inestimable value to those whose occupation compels them to go from place to place where the temperature is continually changing; for, no matter how high or how low the temperature of the surrounding air is, the skin is perfectly protected against any sudden change.

I do not wish to be understood as detracting in the least from Professor Jaeger's due deserts; for he is entitled to great credit for what he has done in insisting upon the value of wool as a material to be worn next the skin. But he is simply re-echoing what Count Rumford said a century ago, which I have already quoted to you this evening. He has founded no new system; he simply insists that pure fine wool is better than the mixtures we have been using.

THE  
NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, APRIL 23, 1892.

CRANIECTOMY IN MICROCEPHALY.

In a recent paper on microcephaly M. Lannelongue strongly affirms the belief that the condition is due to a maldevelopment of the brain, and that the changes in the cranium are secondary, thus agreeing with Broca and others. Although the primary defect may not be in the cranial bones, there is abundant evidence in many cases that the brain is exposed to abnormal pressure. Believing this to be true, Horsley, as reported in the *British Medical Journal* for September 12, 1891, decided to operate upon a patient under his care. The child was three years old, usually restless, and never happy when quiet. He had an idiotic expression, and often made fretful noises, and placed his hands to his head, as if in pain. He was unable to swallow unless the food was pushed well back into his throat. His muscular development was excellent. The head was decidedly microcephalic, but symmetrical. The pupils were unequal.

An operation having been determined upon, an incision through the scalp, to the left of the median line, was made, extending from the frontal eminence backward. The flap was turned back and a strip of periosteum removed, half an inch broad and four inches long, tapering at the points. The underlying bone was removed along the same lines. The dura mater was exposed and bulged slightly. Healing of the wound was perfect. Undoubted improvement was soon noticed in the child's intelligence and general behavior, and the result was distinctly in favor of the opinion expressed by Lannelongue.

In Mr. Horsley's second case the result was less favorable. At the time of operation the child was seven years old. At its birth, which had occurred at the seventh month of gestation, there had been no fontanelles. From the eighth month it had been subject to convulsions. Its intelligence was slight and it was unable to speak. It was restless, often passionate, and decidedly idiotic in appearance. The head was of fair size, but the frontal region was very small.

In the operation a portion of bone was removed similar in shape to that in the first operation. A transverse incision was also made along the coronal suture as far as the pterion, and a narrow strip of bone removed. This was done with a view of relieving the speech center. During the operation the pulse became quick and irregular and the respiration was accelerated. These symptoms continued, hyperpyrexia developed, and the patient died.

From his own experience and from the collation of published cases Mr. Horsley is convinced that the operation should be performed in all cases, as the condition is otherwise hopeless and interference has evidently secured notable improvement in some instances.

## CAN THE PERIOD OF DESQUAMATION IN SCARLET FEVER BE SHORTENED?

It is the general belief that particles of cuticle cast off during the period of desquamation are active sources of infection. It has been alleged that the free use of antiseptic gargles and mouth-washes, together with the removal of epidermic scales as rapidly as they are formed, will destroy all contagion. It is the custom of many physicians to have the body bathed daily with warm water and anointed with oil or carbolized vaseline. A three-per-cent. ointment of carbolic acid, to which a little thymol is added, is said to make an admirable preparation for this purpose. This undoubtedly reduces to a great degree the risk of infection to others. That it materially shortens the period of desquamation is doubtful, though it is said that it tends to avert the sequelæ.

Jamieson, who has written much upon the subject, in an article in the *Lancet* for December 12th, proposes resorein as an agent that will actually accelerate desquamation. Its power to cause the outer layers of the epidermis to separate without injury to the deeper parts is well known. Used in the form of an ointment, it has not been found to have this result in scarlet fever, but in combination with soap it is said to be very active. Salicylic acid must be added to render this soap stable. In this form resorein seems to shorten the desquamative period decidedly. The soap should be used with warm water, and after it has been thoroughly washed away with clear water the body should be anointed with some simple oil.

## MINOR PARAGRAPHS.

## LEPROSY IN MINNESOTA.

WE would call the attention of those health authorities whose notions of leprosy are apparently contemporary with those of the first century of the Christian era to an article in the *Lancet* for March 26th, that has been indorsed by the well-known secretary of the State Board of Health of Minnesota, Dr. Hewitt, and by that excellent sanitarian, Dr. Henry B. Baker, of the Michigan State Board of Health. The article in question is by Dr. Gronvald, of Minnesota, and describes the experience of that State during the past forty years with the lepers among its Scandinavian population. It is stated that all leprosy persons are registered and kept under observation, and all suspicious persons are visited by inspectors of the State board. The only thing that the board requires is for the affected person to have his own bed and utensils. And yet, with so little interference with the freedom of the individual, there are but eighteen cases of leprosy in the State; in none of the descendants of lepers has there been any sign of the disease discovered; no leper has been born in Minnesota; and so no ground has existed for the exhibition of officious zeal in declaring a patient to be an outcast and treating him as such.

## A NEW METHOD OF ENTERORRHAPHY.

IN the *British Medical Journal* for April 2d Mr. F. Bowrenman Jessett reports a new method of enterorrhaphy with decalcified-bone tubes. The latter are of cylindrical form, one end flaring so that its diameter is double that of the opposite end, and the length of the two tubes is two inches and a half.

He designates the tubes as male and female, the former consisting of two parts: a cylindrical portion fastening into the proximal end of the intestines, and a sliding cylinder or spur that enters the female tube. In the flaring end four holes are drilled, through which pass two long threads of chromicized gut, armed with needles at each end. The intestine is excised, and the male tube is inserted into the proximal end of the intestine as far as the flange, the spur projecting beyond the divided end; the threads are passed through all the coats from within outward and held by clamp forceps, while the female tube is in like manner introduced into the distal end. The spur of the male tube is now passed into the female tube, the corresponding threads are tied, and the proximal end of the intestine is steadied with the left thumb and finger, while with the right thumb and finger the distal end is slipped over the proximal for a quarter or half an inch. With four quilt chromicized gut sutures the intestine is sewed and the operation completed. While this operation seems simple, the necessity of having prepared tubes of different sizes on hand presents the same objection that has been urged against Senn's plates.

## INDURATION OF THE STERNO-CLEIDO-MASTOID MUSCLE IN THE NEW-BORN.

DR. CLARENDON RUTHERFORD, professor of descriptive anatomy in the College of Physicians and Surgeons, of Chicago, has sent us an account of another case in which this condition was observed, and under circumstances similar to those recently reported. It occurred in May, 1890, in a first child, the head and shoulders of which were large. The induration was on the right side and extended from the clavicle upward about two inches. The muscle was somewhat tender on manipulation. The face was slightly turned to the left side and the head drawn toward the right shoulder. The swelling was first noticed during the fourth week after delivery, which was instrumental. The umbilical cord was around the neck, and the traction on the head and shoulder might have done the damage. The induration disappeared in about four weeks, after the use of an ointment of sodium iodide, potassium iodide, and vaseline. The child did not grow until after the disappearance of the swelling. There were no glandular enlargements.

## METALLOTHERAPY IN A CASE OF HYSTERIA.

IN the *Gazette des hôpitaux civils et militaires* for April 2d, Dr. Moricourt gives a minute history of a case of hysteria major in which, after long-continued treatment of various sorts, the patient was hypnotized and, metalloscopy being practiced, found to respond to aluminium and especially to gold. Gold coins were accordingly employed, applied to the forearms, and slow but complete recovery took place. On examination after the lapse of more than a year from the time of discontinuing treatment, the patient, a girl of nineteen, was found still quite free from hysterical symptoms, except that she could not help laughing whenever a funeral procession passed.

## THE INFLUENCE OF PURPURA HEMORRHAGICA ON MENSTRUATION AND PREGNANCY.

IN the concluding part of volume xxxiii of the *Transactions of the Obstetrical Society of London*, for the year 1891, we find, a carefully prepared article by Dr. John Phillips dealing that rare occurrence, purpura hemorrhagica as a complication of the generative functions in women. Dr. Phillips thinks the following conclusions justifiable: 1. That the prognosis in cases of

pregnancy complicated by this disease is extremely grave, the large majority proving very rapidly fatal. 2. Death may be due to post-partum hæmorrhage or to some constitutional condition, allied to septicæmia, of the nature of which we are so far ignorant. 3. That abortion or premature labor inevitably takes place, but at variable periods, owing either to the serious general disturbance, or to hæmorrhage into the placenta. 4. That the ordinary purple rash may be modified somewhat, first appearing as a bright red stain, darkening in a few hours' time. 5. That apparently, so far as has been observed, the disease is not, as a rule, transmitted to the fœtus; but that it may be classed as one of the causes of fœtal mortality *in utero*.

#### THE ETIOLOGY OF PUERPERAL ECLAMPSIA.

In the *Comptes rendus hebdomadaires des séances de la Société de biologie* for March 25th M. Combemale and M. Bué, of the clinical laboratory of the Lille faculty of medicine, give brief accounts of four cases of puerperal eclampsia in which they found the *Staphylococcus pyogenes aureus* or the *Staphylococcus pyogenes albus*, especially the latter, in the blood, either during or immediately after labor, and succeeded in cultivating it. The authors do not draw the positive conclusion from these few facts that the micro-organism is the cause of the convulsions, but they intimate that that is probable.

#### THE CITY BOARD OF HEALTH.

CERTAIN resignations of officers are announced as having recently being made "by request," and it is intimated that the requests were made on account of the officers' political affiliations being distasteful to the powers that be. In another instance an excellent officer, a physician of high attainments and of long experience in the board's employ, is said to have been made to change places with his deputy. We hope it will be shown that the newspapers are wrong in attributing these changes to political motives, or at least that the medical members of the board of commissioners protested against them.

#### ITEMS, ETC.

The American Pædiatric Society will hold its fourth annual meeting in Boston on the 2d, 3d, and 4th of May, in the Boston Medical Library Association Building, No. 19 Boylston Place. The preliminary programme gives the following titles: The president's annual address, by Dr. William Osler, of Baltimore; Experiments as to the Value of Nascent Ozone in Certain Forms of Diseases of Children, with Demonstration of an Efficient Generator, by Dr. Augustus Cailé, of New York; Manifestations of la Grippe in Children, by Dr. C. Warrington Earle, of Chicago; An Epidemic of Alopecia in a School of Girls, by Dr. C. P. Putnam, of Boston; a discussion on The Relation of Rheumatism and Chorea, by Dr. C. W. Townsend, of Boston, Dr. M. Allen Starr, of New York, and Dr. Samuel S. Adams, of Washington; The Nomenclature of Diseases of the Mouth, by Dr. T. M. Rotch, of Boston; Report of the Committee on Nomenclature of Stomatitis; Pseudo-diphtheritic Processes, by Dr. W. D. Booker, of Baltimore; The Treatment of Diphtheria by Sublimations of Mercury, by Dr. Dillon Brown, of New York; Typhoid Fever in Children under Two Years, by Dr. W. P. Northrup, of New York; Typhoid Fever in Children, by Dr. C. Warrington Earle, of Chicago; Typhoid Fever in Infancy, by Dr. W. S. Christopher, of Chicago; Acute Emphysema in Children, with Report of Cases, by Dr. F. Forchheimer, of Cincinnati; Pre-tubercular Anæmia, by Dr. B. K. Rachford, of Newport, Ky.; Prevention *versus* Medication in the Management of the Diseases of Children, by Dr. I. N. Love, of St. Louis; Syphilitic Broncho-stenosis, by Dr. A. Seibert, of New York; A Simple Method for Clinical Examinations of Breast Milk, by Dr. L. Emmett Holt, of New York; Sacro-coccygeal Tumor in a Child Three Weeks Old; Op-

eration; Recovery, by Dr. F. Huber, of New York; Two Tracheal and Bronchial Casts, by Dr. F. Huber, of New York; A Case of Death from Laryngismus Stridulus in Incipient Rhachitis, by Dr. Samuel S. Adams, of Washington; and The Value of Milk Laboratories for the Advancement of our Knowledge of Artificial Feeding, by Dr. T. M. Rotch, of Boston.

**The Presbyterian Hospital.**—Appointments on the medical staff have recently been made as follows: Dr. Frederick E. Lange, consulting surgeon; Dr. Francis P. Kinnicut, Dr. William P. Northrup, and Dr. Walter B. James, visiting physicians; and the following-named gentlemen as consultants in special departments: Dr. T. Gaillard Thomas in gynecology, Dr. M. Allen Starr in neurology, Dr. Francke H. Bosworth in laryngology, Dr. Charles Stedman Bull in ophthalmology, Dr. Albert H. Buck in otology, Dr. Newton M. Shaffer in orthopedics, and Dr. George Thomas Jackson in dermatology.

**The Grant Monument and the Medical Profession.**—A meeting of "representative physicians and surgeons of New York city" was held at the Holland House on Wednesday afternoon, for the purpose of securing the co-operation of physicians in the work of providing for the construction of General Grant's tomb.

**The Brooklyn Surgical Society.**—At the meeting of Thursday evening, the 21st inst., the special order of business was a paper by Dr. George Wackerhagen.

**The Societe de biologie.**—At the meeting of March 26th Professor Chauveau was elected president for the term of five years, as the successor of Professor Brown-Séguard.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 10 to April 16, 1892:*

WELLS, GEORGE M., First Lieutenant and Assistant Surgeon, is relieved from duty at San Carlos, Arizona, and ordered to report in person to the commanding officer, Fort Grant, Arizona, for duty at that station.

GLENNAN, JAMES D., First Lieutenant and Assistant Surgeon, is relieved from duty at Camp Oklahoma, and ordered to Fort Sill, Oklahoma Territory, for duty at that station, relieving Captain Francis J. Ives, Assistant Surgeon, who, on being so relieved, will report in person to the commanding officer at Fort Sheridan, Illinois, for duty at that post. S. O. 86, A, G. O., April 12, 1892.

CHAPIN, ALONZO R., Captain and Assistant Surgeon, is granted leave of absence for three months on surgeon's certificate of disability.

GORGAS, WILLIAM C., Captain and Assistant Surgeon, is granted leave of absence for two months, to take effect on or about May 1, 1892, with permission to apply for an extension of one month.

ARTHUR, WILLIAM H., Captain and Assistant Surgeon, is relieved from duty at Fort Grant, Arizona, and ordered to Vancouver Barracks, Washington, for duty as Post Surgeon at that station, relieving Captain Louis Brechemin, Assistant Surgeon. Captain Brechemin, upon being relieved by Captain Arthur, will return to his proper station, Presidio of San Francisco, Cal.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending April 16, 1892:*

DIXON, W. S., Surgeon. Ordered to the Smithsonian Institution.

#### Society Meetings for the Coming Week:

MONDAY, April 25th: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

TUESDAY, April 26th: Louisiana State Medical Society (first day—New Orleans); Medical and Chirurgial Faculty of Maryland (first day—Baltimore); Texas State Medical Association (first day—Tyler); New York Academy of Medicine (Section in Laryngology and Rhinology); New York Dermatological Society (private); Buffalo Obstetrical Society; Medical Society of the County of Putnam (quarterly), N. Y.; Boston Society of Medical Sciences (private); Hunter-

don, N. J., County Medical Society (Flemington); Litchfield, Conn., County Medical Society (semi-annual).

WEDNESDAY, *April 27th*: Louisiana State Medical Society (second day); Medical and Chirurgical Faculty of Maryland (second day); Texas State Medical Association (second day); New York Surgical Society; New York Pathological Society; Metropolitan Medical Society (private); American Microscopical Society of the City of New York; Medical Society of the County of Albany, Auburn, N. Y., City Medical Association; Philadelphia County Medical Society; Gloucester, N. J., County Medical Society (quarterly); Middlesex, Mass., North District Medical Society (Lowell).

THURSDAY, *April 28th*: South Carolina Medical Association (first day—Georgetown); Medical and Chirurgical Faculty of Maryland (third day); Louisiana State Medical Society (third day); Texas State Medical Association (third day); New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopædic Society; Hospital Graduates' Club (New York); Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private—annual); Hartford, Conn., County Medical Association (annual); Pathological Society of Philadelphia.

FRIDAY, *April 29th*: South Carolina Medical Association (second day).

SATURDAY, *April 30th*: South Carolina Medical Association (third day).

#### Answers to Correspondents:

No. 380.—The *Aseclpiad* is published quarterly by Messrs. Longmans, Green, & Co., of Paternoster Row, London, and sold for two shillings and sixpence a number. The American agents are Messrs. P. Blakiston, Son, & Co., Philadelphia, and Messrs. Cupples, Upham, & Co., Boston.

## Reports on the Progress of Medicine.

### CUTANEOUS AND VENEREAL DISEASES.

BY SOPHIE KUPFER, M. D.

**The Treatment of Eczema by Thilanine** is the subject of a paper by Dr. Saalfeld (*Therap. Monatsheft*, November, 1891). Thilanine is obtained by the action of sulphur upon lanolin, and contains three per cent. of sulphur. It is a yellowish-brown ointment, having the consistency of lanolin. It is of value in superficial inflammations of the skin, and is advantageously substituted for the inert ointments, as it is more energetic in action. The author has used it in several cases of eczema, and has never found it to produce any irritation, while it has always yielded excellent results. In other cutaneous affections—such as herpes zoster, syccosis vulgaris, and a case of chrysoarobin dermatitis—he has likewise obtained excellent results from its use.

**Nitrate of Silver for Weeping Eczema.**—Dr. Leven (*Therap. Gaz.*, Feb. 15, 1892, p. 114) recommends the use of a one-per-cent. solution of nitrate of silver in obstinate cases of weeping eczema. Several applications are to be made during the day, the part to be covered with a bismuth ointment in the intervals.

**Eczema of the Face and Scalp in the Infant** is treated by Dr. Baumel (*Nouv. Montpel. méd.*, Jan. 2, 1892, p. 19) in the following manner: The hair is cut off and a hood of oil-silk is worn during the night. This hood favors perspiration, and the secretions soften and loosen the crusts. Simple poultices will accomplish the same object. The crusts are then very simply detached by washing with soap and water in the morning. The following ointment is then applied twice daily: R Vaseline, ℥j; iodoform, gr. xv to ℥j, according to the age of the patient. He gives internally a teaspoonful of the syrup of horse-radish root twice daily, and regulates the nursing and diet.

**Exfoliative Dermatitis.**—Dr. Stephen Mackenzie (*Lancet*, Jan. 2, 1892, p. 27) describes a cuticular glove, obtained from the hand of a patient fifty years of age. He had shed the skin of his hands at regular intervals twice during the year. The exfoliation was preceded by redness and pain in the parts, and an eruption of red spots.

**The Contagiousness of Leprosy** is the subject of an article by Dr. Thin (*Lancet*, Jan. 16, 1892, p. 134). He investigates the origin of leprosy in the town of Parcent, Spain, which, now a leper colony, was free from the disease in 1850. At that time a leper settled in Parcent and became intimate with another man, a native of the town. They ate and drank from the same dishes and occupied the same bed. Within a year the latter had contracted the disease, and from this nucleus leprosy spread, until, at the date of observation, sixty cases of the disease had occurred, and forty-five persons died. The intimates of the person mentioned were the first to be affected, while those who shunned his society remained free from the disease. The disease likewise spread to a neighboring town. Dr. Thin also relates the case of a healthy infant who contracted the disease from a wet-nurse, and who in turn infected his brother.

**Amygdalitis and Cutaneous Eruptions.**—The connection between these affections is the subject of a paper by M. Le Gendre, in *L'Union méd.* (Jan. 21, 1892). He notes a case of amygdalitis in a woman, aged thirty-three years, in the course of which several successive eruptions of purpura and papular erythema appeared. They ended when the amygdalitis disappeared. The patient had mild fever, fugitive pains in the joints, and marked debility. He reports three other cases, in the first of which an erythema multiforme appeared on the fourth day of a follicular amygdalitis; in the second, a month had elapsed before the appearance of articular pains and purpura, the patient having been in a very debilitated condition in the interim. The third case was that of an attack of amygdalitis that appeared between two eruptions of erythema polymorphum. M. Le Gendre urges the investigation by bacteriologists of the connecting link between tonsillar and cutaneous manifestations.

**A Case of Traumatic Pemphigus** is recorded by Dr. Phillippi (*Monatsheft für prakt. Dermat.*, i, 1892, 42). The patient, a woman of thirty-one years, complained of severe pains in the feet and legs, more pronounced after she had been standing or walking for any length of time. An eruption of vesicles then appeared upon the dorsal surface of both feet and on the lower third of the leg. A large serpiginous blister was found when she presented herself for examination, and several pigmented spots, of about the size of a quarter of a dollar, where a crop of blisters had been.

**Pyrogallic Acid in Psoriasis.**—Dr. Grellety (*Gaz. méd. de Paris*, Feb. 6, 1892) gives the following formula for the local treatment of psoriasis: R Salicylic and pyrogallic acids, āā ℥jss.; alcohol and ether, q. s. to dissolve; collodion, ℥ijss. This preparation has no toxic properties.

**Antiseptics in Skin Diseases.**—In an article in the *Rev. gén. de clin. et de théor.* Dr. Arnoz lays down the following general rules for the treatment of diseases of the skin: The general indications are: To obtain cutaneous and intestinal antiseptics; to relieve itching; to remove the thick scales in certain diseases; to relieve the congestion or to stimulate cutaneous circulation; to apply certain specifics for destruction of irreparable lesions; to use for this end internal or external medicaments, not very numerous in all; and to prescribe diet and heat cures. As for antiseptics, in simple cases, in which no special action is required, he recommends boric acid. Its action, he asserts, is sufficiently antiseptic, and, though it is not very energetic, it is neither irritant nor toxic. To produce sealing of the skin he uses salicylic acid or tincture of iodine. In syphilitic ulcerations, mercury, and in tubercular, iodoform are used.

**Hydrotherapy and Nerve Remedies in Dermatoneuroses.**—M. Jaquet (*Rev. gén. de clin. et de thérap.*, No. 8, 1892), after applying the usual remedies in a case of lichen planus, had recourse to hydrotherapy with a very good result. He had, during a month and a half, treated the patient with baths, Fowler's solution, etc., with no result. He then ordered a daily douche of a temperature of 95° F., to be followed by a short cold douche. In a few days a great change took place. The itching was stopped, and the eruption began to disappear during the third week of treatment. The treatment lasted six weeks, when the patient was completely restored. Five months later a relapse occurred, which subsided rapidly upon employing the douches. The action was, in his opinion, that of regulating the nervous system, and thus relieving the severest symptom of the disease—viz., the pruritus. M. Jaquet calls

attention to the nerve remedies which are very efficacious in itching affections. Antipyrine and the bromides are of great value.

**Syphilitiform Erythema** is, according to M. Fournier (*Rev. gén. de clin. et de thérap.*, No. 8, 1892), a disease which is often confounded with true syphilis. It develops in children between the ages of three and eight months, and may appear suddenly in a child whose health has been good, but who suffers (in most cases) from diarrhoea. The site it occupies is the genital region and the internal surface of the thighs, in particular the cutaneous folds. It begins as a papulo-vesicle, which resembles closely a vaccine papule. The vesicles may be isolated or in groups, but they gradually coalesce and form one large lesion. In the second stage the center becomes depressed, the vesicle ruptures, and the surface is eroded and, when not properly treated, simulates a moist papule. Generally, the affection remains a purely local one, though in some cases the glands become involved. Usually a second crop appears at the end of several days, passing through the same succession as the preceding one. When treated, it lasts at least a week before cicatrization occurs. When neglected, its course is long. The treatment should be only local—cleanliness, washing with borie-acid solution, and dressing with bismuth, zinc oxide, salol, or iodoform. The diagnosis is of the utmost importance, as it is very undesirable to institute mercurial treatment in non-syphilitic children, particularly when diarrhoea is present. A careful family history should be obtained, and if the parents are healthy, the diagnosis is easy to make. If acquired syphilis is suspected, a very careful examination will reveal the initial lesion. When no previous history can be obtained, other signs of syphilis must be looked for. Deformities, coryza, mucous patches in the mouth, all may aid in the diagnosis.

**Cod-liver Oil in Lupus Vulgaris.**—A woman, thirty-three years of age, had a patch of lupus vulgaris on the left cheek, which was cured by the scraping method. The right cheek then became similarly affected. Iodoform was used, but with no success (*Rev. gén. de clin. et de thérap.*, No. 3, 1892). M. Zilgien then applied the following dressing. He dipped a band of iodoform gauze into cod-liver oil and alternated this dressing daily with simple iodoform powder. Wherever the oil was applied, rapid cicatrization took place.

**A Rare Form of Skin Disease** is described by Dr. Kenwood in the *Lancet* (Jan. 9, 1892). It is an aberrant form of urticaria, occurring as the consequence of a severe body chill. No concomitant derangement of the digestive or reproductive organs was found, though there was an accentuation of the color and acidity of the urine. When seventeen to eighteen years old, the patient first noticed the occurrence of swellings whenever she had a chill. Otherwise she was in excellent health and of a slightly florid complexion. The eruption consisted of wheals, six inches in diameter, appearing three days after the chill, when the other effects were somewhat spent. They occurred upon any part of the body. The lips and eyelids, particularly the lower eyelids, were frequently attacked. The pharynx was involved upon one occasion. The area to be affected first assumed a slight blush, sometimes bright like erythema, but more generally of a dusky hue. A faint tingling pain manifested itself at this time. When rubbed, the center rose, became relatively blanched, and then the lesion spread rapidly by an indefinite border until it reached the limit of its extension. It now appeared as a pale swelling, surrounded by a faint red line. The tingling sensation, which was always slight, was greater in the stage preceding the swelling, and diminished gradually, disappearing when the wheal reached its maximum. At this stage there was no subjective sensation of any kind, unless the wheal was rubbed or pressed. The duration was two days in bad attacks, but the lesions had come and gone in as many hours. They left no trace. Sometimes, early in the attack, friction over an apparently normal area produced wheals. The feature of special interest in the case was that some of the swellings had assumed the character of a condition described as acute circumscribed cutaneous œdema. There were present in most attacks three or four œdematous tumefactions of the skin and subjacent tissue, firm and knobby in consistency, with ill-defined borders, and slightly paler in hue than the surrounding skin. They pitted very slightly upon pressure. Their favorite site was the skin over the deltoid muscle of the arm, and that over the buttocks. In a recent attack, swelling of the tongue was caused by one of them. They were never less than two inches and a half in diame-

ter, and were generally of an oval shape. Their similarity to the wheals was shown by their changes of development, the rapidity of their appearance and disappearance, and the common cause producing both. There was at first a blushing area, then a rapid swelling, growing paler as it increased in size, and finally the surrounding zone of skin became slightly redder in color. There was no defined border, and subjective sensations were not present.

The author, considering the various features of the case, concludes that it is a hybrid of the following three conditions: (1) Common acute urticaria, (2) urticaria gigans, (3) acute circumscribed œdema. As the patient was of a somewhat rheumatic constitution, the treatment instituted was with a combination of salicylate of sodium and iodide of potassium.

**Heat in the Treatment of Syphilis.**—Dr. Aussass (*Jour. des mal. cut. et syph.*, January, 1892) presented before a society a young man, seventeen years of age, who had become infected from a wet-nurse. From the age of fifteen years on he had had a persistent headache, which yielded neither to mercury nor to large doses of iodide of potassium. Residence in a warm climate improved him a little. The doctor then ordered daily hot baths in combination with mercurial friction, and obtained a brilliant result in a very short time. The benefit was due, in his opinion, to the more rapid elimination of the mercury under the influence of the hot baths, and to an increased receptivity of the body for the remedy.

**Primary Chancre of the Cheek.**—A case is reported by Dr. Shield (*Lancet*, Jan. 30, 1892) occurring in a widow, thirty-four years of age. No history of infection could be obtained. All that was known was that the sore had existed for two months. It was a dusky-colored swelling, of the size of a florin, and situated in the center of the left cheek. The edges were sharply defined and there was neither ulceration nor discharge. The submaxillary glands were enlarged, and the skin was covered with a dusky syphilitide. Mercurial treatment was instituted, and under it the rash had faded and the chancre had become reduced in size.

**Succinimide of Mercury for Injections.**—In the *Arch. für Derm. und Syph.* (January, 1892), Professor de Amicis gives a formula for the hypodermic injection of mercury, which he has used with great success. He injects a one-per-cent. aqueous solution of succinimide of mercury, to which he adds a one-per-cent. solution of cocaine. It yields good results in both secondary and tertiary lesions. Its activity is as great as that of the bichloride, and it produces much less pain and irritation.

**The Modern Treatment of Syphilis.**—Dr. Finger (*Med.-chirurg. Wochenschr.*, Feb. 5, 1892) advocates the use of baths in the pustular and ulcerated forms of the disease. He considers the absorption of mercury in considerable quantity as the first advantage of this method, its local action upon the lesions themselves the second. He dissolves two and a half to eight drachms of bichloride of mercury in about fifteen ounces of water, and adds the whole to a bath having a temperature of 78° to 80° F. This temperature should be maintained by the addition of hot water. The patient remains in the bath from half an hour to two hours. It is taken daily and is to be followed by an hour's rest in bed. If the lesions are only upon one limb, an arm or foot bath will be sufficient. For this a drachm and a half to three drachms of the bichloride should be used.

For children the author advises a mode of treatment rarely employed—viz., the application of mercurial plasters. The back, chest, arms, and legs are surrounded in definite rotation with the plasters, which are left *in situ* for several days until they fall off spontaneously. Treating of the hypodermic method, he calls attention to the superiority of the intramuscular method over the subcutaneous injections of insoluble salts. He warns against the danger of cumulative action in these cases. The mercurialism can not be met excepting by surgical means involving an incision over the site of injection, and removal of the injected material. He advocates the use of a one-per-cent. solution of corrosive sublimate plus a twenty-per-cent. solution of common salt as the best preparation for injection. A solution composed of sodiodate of mercury, fifteen grains; potassium iodide, twenty-five grains; distilled water, two drachms and a half, is the most energetic, according to him, and is sufficient, being injected five to six times at intervals of a week, to accomplish a complete cure.

**Aristol for Venereal Ulcers** is recommended by Dr. Güntz (*Memo-rab.*, Jan. 23, 1892) as a substitute for iodoform. He considers iodoform the best remedy, but recognizes the objection to its odor. Aristol should not be remedy in the form of an ointment, but should be applied directly to the wound. It is insoluble in water, but forms a tough brown pap with olive oil, which is, however, difficult of application. The undissolved powder itself is inert. Therefore the ulcer should be strewed with the powder, and a drop of olive oil be allowed to fall slowly from a glass rod upon it. Without waiting for the solution to be effected, the ulcer is promptly covered with some fine impermeable tissue, under which the solution takes place slowly. No cotton or charpie should be applied to the ulcer. If the secretions are very profuse, or if the ulcer is in an unfavorable location, this dressing must be secured by means of court-plaster. The application should be renewed twice daily, after careful removal of that previously applied. Its advantages are that it is painless, odorless, and non-irritating, and that there are no inconveniences attaching to its use. Painful ulcers become painless, and previously bedridden patients become able to go about after its use. If, however, as is the case in eroding or torpid ulcers, the healing tendency is not sufficiently rapid, recourse to iodoform must be had.

Although aristol is not curative in soft chancres, nevertheless, where it is substituted for iodoform, there is no danger that the lesions will assume a more serious character. This happens frequently when mercurial ointments are used. In hard chancres its action is better. But it is of especial value in secondary lesions, in ulcerating gummata, in tubercular syphilides, etc. Although, if continued long enough, this treatment will effect a cure, nevertheless it is hastened by the internal administration of antisyphilitics.

**Ointments.**—Dr. Wende (*Buff. Med. and Surg. Jour.*, January, 1892) lays down the following essentials for a good ointment basis:

1. *Proper Consistence.*—It must be soft, smooth, and pliable, readily admitting of a uniform application.
2. *Homogeneity.*—It must be perfectly homogeneous, free from grittiness and irritating bodies.
3. *Durability.*—It must not show a tendency to change its physical and chemical peculiarities on exposure or long keeping.
4. *Miscibility.*—It must be capable of easily receiving the ingredients to be combined or incorporated.
5. *Power of Imbibition.*—It must be capable of absorbing liquids, especially water.
6. *Limitations of Temperature.*—It must have a melting-point somewhat higher than the temperature of the body. It must not liquefy.
7. *Inability to produce Irritation.*—It must be perfectly bland and neutral in reaction.

**Syphilis and Heredity.**—Dr. Molfese (*Il Progresso medico*, Jan. 20, 1892) cites the case of a young man, twenty-three years of age, who contracted syphilis and was treated with protiodide of mercury and ealomel. Intense headache, evening fever, and profuse night-sweats ensued after a short period. Inguinal, cervical, and submaxillary adenitis was present. There were mucous patches on the sides of the tongue, on the pillars of the fauces, on the soft palate, and at the angles of the mouth, and a maculo-papular syphilide covered the body. The bichloride of mercury was then injected, and marked improvement was noted after the tenth injection. Disappearance of the headache, fever, and eruption marked the improvement, but the mucous patches persisted, breaking out anew in another place when they disappeared from a previous one. During two years of observation it was found that, if for any period, however short, there was an interruption of the injections, the submaxillary and inguinal glands became swollen and painful. Not fully two years after the date of infection the patient married a healthy woman, who, ten months later, gave birth to a healthy child. The patient had, immediately preceding marriage, subjected himself to a treatment of eighty injections. Neither mother nor child showed any evidence of syphilis. The woman, becoming pregnant for the second time, aborted at five months, and two months later again conceived, and aborted at three months. After the first abortion glandular enlargement was found; she lost flesh, and had rheumatoid pains. Two months after the second abortion she again conceived, and was delivered at term of a healthy child. The woman underwent no treatment,

with the exception of taking a few ounces of iodide of potassium. The husband received fifteen hypodermic injections, but this was when the pregnancy had already advanced to six months. Dr. Molfese concludes, therefore, that the mother was infected, not from the husband, but from the first foetus; and that a syphilitic father who has borne to him one healthy child can not count upon immunity from the disease for other offspring.

## Miscellany.

**Hippocrates** was the theme of a "bibliographical demonstration" in the Library of the Faculty of Physicians and Surgeons of Glasgow, on November 23, 1891, by Dr. James Finlayson, the honorary librarian. Written out from memory, it appears in the April number of the *Glasgow Medical Journal*. The greater portion of it is as follows:

*Value of Historical Studies.*—In resuming our "bibliographical demonstrations" to-night, I wish to take the present opportunity of saying that I have long desired to try this method of directing the attention of some of our students or young graduates to the history of medicine. I believe that the history of our art is not only full of interest to us as students, but that it is of great importance to us as practitioners. To those, especially, who have only recently entered on practice, it seems to me that some knowledge of the history of medicine affords the only means of supplying the place of personal experience, in judging of the ever changing phases of our art. The history of various revolutions in theories and in practice, and the indications thus afforded of the lines on which steady and substantial progress has been made since the earliest times, or, on the other hand, of the pitfalls into which our predecessors have been entrapped, seem to me the only way of securing for the inexperienced any sense of "perspective" in looking at new facts and new ideas as they arise.

But the history of medicine seems never to have been much of a success in the schools of Scotland; even when taught, as it has been in Edinburgh, by a man of the greatest eminence and ability, the success is reported to have been dubious, or at least slight. In England, so far as I know, the results have not been much better, although the requirements of the Royal College of Physicians of London in the examination for its membership have kept the subject more alive there than here.

*Method of Bibliographical Demonstrations.*—I have for a long time thought that this subject, like most of our medical subjects, should be approached—if approached at all in the form of lectures—by the practical methods we now adopt in other departments. My own personal experience was that I only began to feel the reality underlying such names as Hippocrates, Galen, Avicenna, Bonetus, or Morgagni, when I was led, during my connection with the medical library in Manchester, to handle the works of the giants of the past. When thus made to realize the substantial character of their contributions, an occasional dip into their writings, if even only to read their title pages, the headings of their chapters, or a short passage on some subject having a special interest at the moment, gave me, from that time, a sense of a certain personal acquaintanceship with the writers, very different from the mere shadowy idea previously gathered from seeing or hearing their names in a book or a lecture. After such a glimpse, one sometimes felt impelled, and certainly more prepared, to gather up from historical or biographical works more detailed information as to the lives and doctrines of those who had left their mark for all time.

In charge of a valuable medical library in this great medical center, I have often thought of trying how far the method of "bibliographical demonstrations" could be made available in stimulating interest and laying the foundations for future study; but the pressure of practical work, of a varied but always of a more urgent kind, has hitherto prevented me from undertaking the experiment. Nearly two years ago I obtained permission from the Council of the Faculty to give demonstrations in the Library to any members of the profession I might think of inviting, but I was only able to make a beginning this winter. The

slight preliminary experiments already made this month seemed so encouraging that I have now ventured, at this third meeting, to enter upon a demonstration of the Hippocratic writings.

Our meeting here is small, but, in my view, that is one of the conditions of success in this plan. We wish the numbers to be such that you can all sit around the table on which the books are placed, see them when demonstrated, and look at them quietly for yourselves after the demonstration is over. I began the demonstrations with old anatomical works containing many curious and attractive illustrations, so as to cultivate this habit of personal examination; in the subject before us to-night the illustrations must be drawn from selected passages which I will read from the books before you.

The next point of difficulty which had to be faced was the selection of an audience. Our over-pressed students can scarcely be expected to take the trouble of learning about anything which "does not pay" at the examinations, although at my second demonstration this winter of books bearing on Physiognomic Diagnosis, to which students were invited, I had a goodly number of them—as many, indeed, as desired. After consideration, it seemed to me that the most suitable audience for my purpose was such as I have to-night—an audience selected chiefly from the residents at the various hospitals here, according as they were understood to be interested in such matters, with the addition of any one else who expressed a desire to come. As most of you here have been more or less associated with me as hospital assistants, I felt that whatever deficiencies I showed in carrying through this new enterprise, I would at least receive a sympathetic hearing and a kindly judgment.

*Peter Lowe's Translation of the Prognostics.*—In this library it may be legitimate to begin a demonstration of the Hippocratic writings by showing you the first translation into English of any portion of them. This was made by Peter Lowe. He published his translation in 1597, and obtained a charter for our Faculty in Glasgow from James VI in 1599. His translation is notable as being the first attempt to render into English, for the use of practitioners, any of the great Hippocratic treatises. But we can not regard it as a very scholarly translation. Indeed, it appears, from the researches of Dr. Creighton, that his translation of the Presages (as he calls the Prognostics) was made neither from the Greek nor Latin, but from the French version by Canappe, published in Lyons in 1552; this, again, was from the Latin edition of Rabelais, and founded on the text of Copus. The source of Peter Lowe's translation is shown not merely by such things as the headings of the chapters in the Presages, but by its association with a translation of the Oath also; and, above all, by the prefixing of the same Life which occurs in Canappe's French translation, but not in Rabelais's edition.\* In this Life, by a curious misprint, "Pereno" occurs in all the four editions of Peter Lowe's translation instead of Zeno (the Eleatic philosopher), who is referred to as a contemporary of Hippocrates.

It is in the Prognostics that the celebrated passage occurs describing what is known as the "facies hippocratica." I will read you Peter Lowe's rendering of it in his translation of The Booke of the Presages of deuyne Hippocrates. I quote from the third edition, but I believe it is the same text as in the first, published in 1597:

*"How the Physitian or Chyrurgian may presage by signes of the Face, in sicknesse.*—It is requisite to consider and contemplate the Face of the sicke. First to know if it be such as in health, or but a little different: and if it be so, the Medicieir Chirurgian may have a good presagment and hope of Recoverie. But if it be greatly altered, and changed, as followeth, hee shall esteeme it in perill and danger of death, when the nose and nostrills are extenuated and sharpened by the same maladie, and the eyes hollow, and the temples, viz., the parts betweene the eares and forehead are cleane, and the skinne of the brow is hard, dry, and loose, and the eares cold and shronke, or almost doubled, and all the face appeareth blacke, pale, livide or leaden, and greatly deformed, in respect of that which it was in time of health."

On reading any rendering of this passage one is at once reminded

\* Some further details on this subject may be found in *Account of the Life and Works of Maister Peter Lowe*, by James Finlayson, M. D. (Glasgow, 1889); also in an article by Dr. Charles Creighton on Falstaff's Deathbed, in *Blackwood's Magazine*, March, 1889.

of the celebrated description in Shakespeare of the death of Falstaff, where Dame Quickly says:

"For after I saw him fumble with the sheets and play with flowers, and smile upon his fingers' ends, I knew there was but one way: for his nose was as sharp as a pen and a' babbled of green fields," etc.—Henry V, Act ii, scene 3.

The question has arisen as to how Shakespeare could have obtained access to the description of the *facies hippocratica*, and it has been suggested that Peter Lowe's English translation may have been available for one who had "small Latin and less Greek." So far as the dates go, they might, indeed, fit in, as Peter Lowe's translation was issued in London in 1597, and King Henry V was first published in 1600. After a full investigation of the subject, however, Dr. Creighton has come to the conclusion that this translation is *not* the source of Shakespeare's phrases.\*

*Chronology—Hippocrates a Reality.*—I have placed on the board some dates to guide you in your ideas of the time, according to the best authorities, when Hippocrates flourished, adding various dates selected from different countries for the sake of comparison:

	B. C.
Hippocrates.....	(about) 460-357
Socrates.....	469-399
Zeno, the Eleatic philosopher, born.....	488
Plato.....	428-389
Aristotle.....	384-322
Roman Decemviri created.....	451
Virginus killed his daughter.....	458
Second return of the Jews under Ezra.....	458

But on looking at such a table one is reminded of important preliminary questions which have been raised—viz., Was there such a man? Were not the Hippocratic writings merely a miscellaneous collection, issued under a traditional name?

The first question seems capable of a satisfactory answer in the affirmative. M. Littré, in his valuable edition of Hippocrates, in the ten volumes now before you, has gone into this matter critically in the elaborate introduction contained in the first volume. M. Littré was a learned member of our profession; he is the same of whom you have all heard as the author of this great French dictionary, in four large volumes, which I show you here. Some of you may also have heard of him as an exponent of the positive philosophy of Comte. M. Littré (vol. i, p. 29) quotes a passage from one of the dialogues of Plato (*Protagoras*), where Socrates is represented as saying to one of his auditors, who happened to be called Hippocrates—

"If for example you had thought of going to Hippocrates of Cos, the Asclepiad, and were about to give him your money, and some one had said to you: You are paying money to your namesake Hippocrates, O Hippocrates: tell me, what is he that you give him money? How should you have answered?

"I should say, he replied, that I give money to him as a physician.

"And what will he make of you?

"A physician, he said." † (Jowett's Translation, second edition, vol. i. Oxford, 1875.)

M. Littré contends that this passage from Plato, who lived shortly after the date ascribed to Hippocrates, proves that Hippocrates was a physician; of the Island of Cos; of the family of the Asclepiade; that he taught medicine, and received fees for doing so; further, that as the words are put into the mouth of Socrates, these two great men must have been contemporaries. This little glimpse shows you the kind of evidence which can be adduced to prove the veritable existence of Hippocrates and his approximate date. Another passage is quoted by M. Littré (vol. i, p. 72) from Aristotle, who, although somewhat later, is still near enough to be an important witness (*Politics*, Lib. vii, cap. 4), "When we speak of the great Hippocrates we understand not the man, but the physician."

\* See *Blackwood's Magazine*, March, 1889.

† M. Littré quotes another passage from Plato (*Phaedrus*) where Hippocrates is spoken of as an individual and as a writer of authority. The passage is quoted also by Dr. Warburton Begbie (*Selections from the Works of*): London, 1882, p. 385.

In his elaborate and learned introduction, M. Littré goes into this discussion in great detail, quoting from Plato, Aristotle, and others; certain phrases in their works being adduced to show that these ancient authors were familiar with certain portions of the Hippocratic writings.

From the necessity of this accumulation of proof, it must be evident to you that there is no *reliable* Life of Hippocrates. Three lives are referred to, the most important being one by Soranus, or rather according to Soranus (*κατά Σωρανόυ*). This has been repeatedly published, and is appended to the edition by Ermerins, as I show you, both in a Greek and Latin text. There are insuperable difficulties in deciding who this Soranus really was. It seems certain that he was *not* the same as the Ephesian Soranus otherwise well known in medical literature, although this biographer is also said to have been of Ephesus; it has been further supposed that there was also a Soranus of Cos, who explored the records of that island, and whose materials were used for the purpose of this biography.

The portraits of Hippocrates are all without authority. I show you some representations copied from busts or antique gems. I also show you portraits prefixed to certain editions of his works, but as none are authentic, we need not linger on this subject.

*Hippocratic Writings: Genuine and Spurious.*—Although the personality of Hippocrates as a physician and an author is clearly established by the best historical evidence, the authenticity of the various treatises ascribed to him is quite open for discussion. The general consensus of critics points to there being three different groups of the treatises bearing his name.

1. Genuine works, undoubtedly Hippocratic.
2. Spurious works, certainly not written by the great Hippocrates.
3. Dubious works.

Of the spurious and dubious works one or two may have been earlier, but the most of such are regarded as being of later production.

It is quite possible that some of the spurious writings of later date may have been "Hippocratic" in the sense of being written by one of that name, although not by our author, who is distinguished sometimes by the adjective "Magnus,"\* to indicate his pre-eminence among all those of the same name, and often, indeed usually, by the adjective "Cos," to indicate the place of his birth.

*Pre-Hippocratic Works.*—The most interesting question as to the authenticity of the writings turns on the date of certain of the works ascribed to Hippocrates being really *before* his time, a subject discussed with great learning by Houdart, Littré, Ermerins, Adams, Greenhill, and others. That there were ancient medical writings *before* Hippocrates may be taken as certain. One of the Hippocratic treatises regarded as undoubtedly genuine by M. Littré (tome i, p. 320) is that *On Ancient Medicine*. His opinion is based on a quotation from the *Phaedrus* of Plato, and is supported by an elaborate argument; this argument is not admitted as conclusive by Dr. Adams; but the latter points out, as an evidence of the reality of an ancient medical literature before the time of Hippocrates, that "Xenophon, who was almost contemporary with Hippocrates, puts into the mouth of Socrates, who was certainly nearly of the same age, the saying that there were many medical works then in existence (*Memorab.*, iv)." If we accept the treatise *On Ancient Medicine* as really by Hippocrates Magnus, its very title may be taken as implying a pre-existing literature. If this treatise is rejected, we have the testimony of another, universally admitted as written by Hippocrates—viz., *The Regimen in Acute Diseases*. In this book the writer begins with the words "Those who composed what are called *The Cnidian Sentences*"; we have thus clear proof of some ancient literature in medicine available for Hippocrates to profit by and criticise. It would seem as if Cnidos had been a rival school to that of Cos, to which latter Hippocrates belonged; and these *Cnidian Sentences* have been supposed to be the analogue in that school of the *Cosan Precognitions* pertaining to Cos. This latter work was long regarded as a production of Hippocrates, but is now supposed by many to be a part of that earlier literature on which our author founded his work.

It could not escape attention that three of the Hippocratic treatises—(1) *The Prognostics*, (2) *The Cosan Precognitions*, and (3) *The Prorrhetics*

\* See the passage already quoted from Aristotle, where he is called "the great Hippocrates."

ies—were in many ways similar. The first was universally regarded as the most perfect, and so at one time the others were ascribed to subsequent and somewhat inferior authors or imitators. The resemblances are well brought out in tabulations, such as I now show you in M. Houdart's book. A critical comparison shows that both the *Prorrhetics* and the *Precognitions* contain the names, in detail, of individual patients from whose cases some special prognostic is drawn, whereas the *Prognostics* contain no such personal details. It seems pretty clear, therefore, that the *Prognostics*, a much more finished production, omitting all personal memoranda, must have followed instead of preceded the other two; and, as the *Prognostics* are universally admitted to be by Hippocrates, we have very probably, in these other two, specimens of the work of earlier observers, by whose labors Hippocrates could profit, and in doing so could fairly enough rear for himself such a surpassing reputation as the "Father of Medicine"; for then, as now, acuteness of personal observation and independence of thought were quite compatible with profiting by the labors of others and the experience of the past. I have already read a short extract to you from the *Prognostics*, describing the "facies hippocratica." This work is undoubtedly one of the greatest and most celebrated of the Hippocratic writings.

*Aphorisms.*—Another equally famous is the *Aphorisms*. I have selected the first and last aphorisms as specimens. The translations which I propose reading to you are from Dr. Adams's admirable rendering; but I avail myself of two of his alternative translations in the first aphorism, as somewhat more impressive, in my view, than those in his text:

I. 1. "Life is short, and the art long; the time is urgent; experiment is dangerous, and decision is difficult. The physician must not only be prepared to do what is right himself, but also to make the patient, the attendants, and externals co-operate."

The first clause, familiar to so many, is recognized by comparatively few, even of the cultured, as being in the works of Hippocrates. The first portion of the aphorism has the gravity of the philosopher; the second shows the practical experience of the physician; I am sure you will find as you go on in the profession that all the difference between success and failure often depends on whether the physician possesses this invaluable power of compelling patient, attendants, and even external circumstances to co-operate with him in the proper management of the illness. Mere knowledge and skill often fail for the want of some measure of this power.

The last aphorism is also celebrated, and I read it to you now, although some doubts exist as to whether it has not crept into the first book of the aphorisms from a continuation by a later writer:

VI. 87. "Those diseases which medicines do not cure, iron (the knife?) cures; those which iron can not cure, fire cures; and those which fire can not cure, are to be reckoned wholly incurable."

*Hippocratic Oath.*—The Hippocratic Oath is so widely known that perhaps it is scarcely necessary to read it; some modification of it was used when graduates in medicine were sworn in at the University here in my time; and even now it survives, to some extent, in the declaration still made by you. It will be better, however, for me to read this short Hippocratic piece in full, so that you may catch its full spirit and meaning. The rendering is by Dr. Adams, whose translations I use here whenever available:

"I swear by Apollo the physician and Esculapius and Health [Hygeia] and All-heal [Panacea] and all the gods and goddesses, that, according to my ability and judgment, I will keep this oath and this stipulation—to reckon him who taught me this art equally dear to me as my parents, to share my substance with him, and relieve his necessities if required; to look upon his offspring in the same footing as my own brothers, and to teach them this art, if they shall wish to learn it, without fee or stipulation; and that by precept, lecture, and every other mode of instruction, I will impart a knowledge of the art to my own sons, and those of my teachers, and to disciples bound by a stipulation and oath according to the law of medicine, but to none others. I will follow that system of regimen which, according to my ability and judgment, I consider for the benefit of my patients, and abstain from whatever is deleterious and mischievous.

"I will give no deadly medicine to any one if asked, nor suggest any such counsel; and in like manner I will not give to a woman a pessary to produce abortion.

"With purity and with holiness I will pass my life and practice my art.

"I will not cut persons laboring under the stone, but will leave this to be done by men who are practitioners of this work.

"Into whatever houses I enter, I will go into them for the benefit of the sick, and will abstain from every voluntary act of mischief and corruption, and, further, from the seduction of females or males, of free-men and slaves. Whatever, in connection with my professional practice, or not in connection with it, I see or hear, in the life of men, which ought not to be spoken of abroad, I will not divulge, as reckoning that all such should be kept secret.

"While I continue to keep this oath unviolated, may it be granted to me to enjoy life and the practice of the art, respected by all men, in all times! But should I trespass and violate this oath, may the reverse be my lot!"

There are two points in this oath to which I wish to call your attention. The opening phrase, "I swear by all the gods and goddesses," has been recognized as mentioned by Aristophanes, where one speaker says: "What better oath than that of the brotherhood of Hippocrates?" The other answers: "Well! I swear by all the gods" (Littre, tome i, p. 31\*). The other point in connection with the oath, to which I direct your attention, is the remarkable passage forbidding those who are thus sworn to cut for the stone. Hippocrates practiced various grave surgical operations, and it has been a matter of wonder that this one should be forbidden. Some, indeed, have sought to solve the difficulty by suggesting that he does not refer to lithotomy, but to castration.†

It is almost certain that the operation referred to was really lithotomy; the separation of this operation from the ordinary practice of surgery is indicated by the Founder of our Faculty here, for Peter Lowe passes it over in his *Discourse of the Whole Art of Chyrurgerie*, which was published while he was in Glasgow in 1612, referring its discussion to his treatise entitled *The Poore Mans Guide*. The operation from the time of Hippocrates till very recently was practiced by a set of men outside of the profession. In the Burgh Records of our city we have the following suggestive entry:

"27th March, 1688.—The said day there was ane testificat produced in favor of Duncan Campbell, subservyit be the haile doctors and most part of the chyrurgians in toune, of his dexteritie and success in cutting of the ston, as also in sounding with great facilitie, and hes given severall proofes thereof within this burgh, whilk being taken to the said Magistrats and Counsell their consideration, they nominat and appoynt him to cutt such poor in toune as he shall be desyred be the Magistrats, in place of Evir M'Neil, who is become unfit to doe the same through his infirmitie."—*Memorabilia of the City of Glasgow*, Glasgow, 1868, p. 258.

*Qualifications and Functions of the Physician.*—With regard to the necessary conditions for the successful study of medicine, I read you the following short extracts from "The Law"; I desire your special attention to the profound wisdom of the last clause:

"Whoever is to acquire a competent knowledge of medicine ought to be possessed of the following advantages: A natural disposition; instruction; a favorable position for the study; early tuition; love of labor; leisure. First of all, a natural talent is required; for when Nature opposes, everything else is vain; but when Nature leads the way to what is most excellent, instruction in the art takes place, which the student must try to appropriate to himself by reflection, becoming an early pupil in a place well adapted for instruction. He must also bring to the task a love of labor and perseverance, so that the instruction taking root may bring forth proper and abundant fruits.

... "But inexperience is a bad treasure and a bad fund to those

\* M. Littre departed from this view of the passage while treating of the oath (see tome ii, p. 48); M. Petrequin, however (*Chirurgie d'Hippocrate*, tome i, Paris, 1877, p. 172), still adheres to this meaning of the passage.

† This question is discussed in an elaborate note, at the end of the oath, by M. Petrequin (*Chirurgie d'Hippocrate*, tome i, Paris, 1877, p. 192); he comes to the conclusion that the oath refers to lithotomy, and that it was proscribed owing to the disasters following its practice at that time.

who possess it, whether in opinion or in reality, being devoid of self-reliance and contentedness, and the nurse both of timidity and audacity. For timidity betrays a want of power and audacity a want of skill. There are, indeed, two things, knowledge and opinion, of which the one makes its possessor really to know, the other to be ignorant."

The following celebrated passage is from the *First Book of the Epidemics* (ii, 5):

"The physician must be able to tell the antecedents, know the present, and foretell the future—must meditate these things and have two special objects in view with regard to disease—namely, to do good or to do no harm. The art consists in three things—the disease, the patient, and the physician. The physician is the servant of the art, and the patient must combat the disease along with the physician."

Objection has been taken to the instruction that the physician should "do no harm" as being unnecessary and too trivial, but after twenty-three centuries the retention of this clause must be held to be still essential by all who have seen much of practice. In connection with this same spirit, I may refer to what has been called the "Hippocratic Paradox." A thesis by G. A. Langguth, *De paradoxico hippocratico* (4to, Wittenberge, 1754), discusses this paradox at some length as you see. The paradoxical passage referred to is found in the treatise on *Articulations* (40), which is regarded as genuine; it occurs in connection with the treatment of injuries to the ears:

"For it is a good remedy sometimes to apply nothing at all, both to the ear and to many other cases."

In connection with these same ideas, I have to call your attention to a passage in one of the Hippocratic treatises; although it is considered to be of a later date than our author himself, this is of little importance under the circumstances; he speaks of Herodius (his own teacher and the inventor of medical gymnastics) as having occasioned the death of not a few patients, affected with fever, while subjecting them to treatment by means of vapor-baths and violent exercises instead of rest (Littre, tome v, p. 303).

The passage in which Hippocrates, according to the usual translation, speaks of "Nature" as the healer of our diseases has been discussed by Professor Gairdner in one of his essays, and subjected to his fruitful criticism. The meaning of the phrase *νοῦσον φύσις ἰητροί* (*Epidem.*, vi, 5) is shown by him to be somewhat different from the general dictum about the "vis medicatrix nature." He shows that what Hippocrates alleges is that "our natures are the physicians (or healers) of our diseases," and he paraphrases it thus: "that normal function is in every instance to be evoked and supported, and protected, as what is usually the only way open to us for effectually overcoming abnormal function."\* This Hippocratic view of our natures being themselves the physicians of our diseases is at present receiving fresh illustrations in the remarkable studies now being pursued regarding the processes which secure "immunity."

*Are any Diseases Sacred or Divine?*—The view taken by Hippocrates of "the sacred disease," as epilepsy was called, is most philosophical. The mysterious outbursts of this remarkable disease by which a person, often in perfect health, is suddenly struck down and given over to the most violent convulsions, which may quickly pass off, so that he can resume his usual course in a short time, have suggested in various ages and countries the idea of some special supernatural agency, whether divine or demoniacal. He begins thus:

"It is thus with regard to the disease called sacred; it appears to me to be nowise more divine nor more sacred than other diseases, but has a natural cause from which it originates like other affections. Men regard its nature and cause as divine from ignorance and wonder, because it is not at all like to other diseases. And this notion of its divinity is kept up by their inability to comprehend it, and the simplicity of the mode by which it is cured, for men are freed from it by purifications and incantations. But if it is reckoned divine because it is wonderful, instead of one there are many diseases which would be sacred; for, as I will show, there are others no less wonderful and prodigious, which nobody imagines to be sacred."

\* W. T. Gairdner, *The Physician as Naturalist* (Glasgow, 1889, p. 260); see also Dr. Warburton Begbie, *Selections from the Works of* (London, 1882, p. 386).

In a similar strain, he writes in the treatise On Airs, Waters, and Places (22), with regard to some disorder prevailing among the Scythians:

"It appears to me that such affections are just as much divine as all others are, and that no one disease is either more divine or more human than another, but that all are alike divine, for that each has its own nature, and that no one arises without a natural cause."

It has been a great puzzle that, with such a clear statement of his views on the subject, Hippocrates should himself, in his *Book of Prognostics* (Lib. i), say that we are to ascertain

"Whether there be anything divine in the diseases."

It has been supposed that he may here use the word "divine" in the sense of atmospheric or pestilential, or that he may be adapting himself, for the time, to the popular language.

*Hippocratic Auscultatory Signs*.—In modern times we are so saturated with physical methods of diagnosis, especially in chest disease, that we can scarcely think of diagnosis without them. Although nearly all these methods have been introduced within this century, there is one, at least, which goes back to ancient times, and is even now termed "Hippocratic succussion." I have marked the passages in Littré's edition so that you may see where this is referred to. In some of the passages it is merely named or alluded to in passing, as a thing well known, but I will render from Littré's translation one passage where the process is described:

"You will place the patient on a seat which does not move, an assistant will take him by the shoulders, and you will shake him, applying the ear to the chest, so as to recognize on which side the sign occurs" (Littré, tome vii, p. 153).

A very similar passage occurs in tome vii, p. 71. Both of these are from the treatise *De morbis* (Lib. iii and Lib. ii respectively). The fact that this sign may be absent in cases requiring operation is recognized and ascribed to the quantity or density of the pus being too great. The bulging and the pain are then to be taken as guiding to the affected side. (Other passages referring to succussion may be found in Littré's edition, tome v, p. 681, and tome vi, pp. 151 and 309.)

The practical importance of succussion seems to have depended specially, in his view, in determining which side to operate on in cases of empyema.

Another passage has been pointed out as referring to auscultatory signs apart from succussion. I will translate for you Littré's rendering of this passage, the exact meaning of which is still involved in considerable obscurity:

"And if applying the ear against the chest, you listen for a long time, it boils within like vinegar" (*De morbis*, Lib. ii; Littré, tome vii, p. 95).

What auscultatory sound this was, which was to guide the operator to the side on which the incision should be made, is not clear. That it really was a *sound* which constituted the sign is clear from the context, and amid various readings M. Littré prefers the word meaning to boil.\*

A sound resembling that made by new leather is described in pleurisy (*De morbis*, ii, 59; Littré, tome vii, p. 93). These and other references to auscultation are given by Dr. Gee in his book on *Auscultation and Percussion* (third edition, London, 1883), p. 100.

*Cheyne-Stokes Breathing*.—It is not in physical signs, but in general symptoms, that the power of observation, undoubtedly pertaining to the Hippocratic school, comes out most strongly. The Prognostics are full of the keenest clinical observation. It is very interesting, and even startling, to read a description of Cheyne-Stokes respiration in those old times. This remarkable form of breathing is generally regarded as being a matter of observation only in recent times, noted by the two great clinical observers whose names it bears. But, according to Dr. Warburton Begbie (*Selections from the Works of*, p. 390), the case of Philiscus, in the *First Book of the Epidemics* (13), as described by Hippocrates, agrees with this type of breathing. It seems to me that Dr. Begbie makes out his case; but I will read the passage in full, from Dr. Adams's translation, so that you may judge for yourselves:

"Philiscus, who lived by the Wall, took to bed on the first day of acute fever; he sweated; toward night was uneasy. On the second day all the symptoms were exacerbated; late in the evening had a proper stool from a small clyster; the night quiet. On the third day, early in the morning and until noon, he appeared to be free from fever; toward evening, acute fever with sweating, thirst, tongue parched; passed black urine; night uncomfortable; no sleep; he was delirious on all subjects. On the fourth, all the symptoms exacerbated; urine black; night more comfortable; urine of a better color. On the fifth, about midday, had a slight trickling of pure blood from the nose; urine varied in character, having floating in it round bodies, resembling semen, and scattered, but which did not fall to the bottom; a suppository having been applied, some scanty flatulent matters were passed; night uncomfortable, little sleep, talking incoherently; extremities altogether cold, and could not be warmed; urine black; slept a little toward day; loss of speech; cold sweats; extremities livid; about the middle of the sixth day he died. The respiration throughout like that of a person recollecting himself, was rare and large, the spleen was swelled up in a round tumor, the sweats cold throughout, the paroxysms on the even days."

Dr. Adams says in a note: "The modern reader will be struck with the description of the respiration—namely, that the patient seemed like a person who forgot for a time the *besoin de respirer*, and then, as it were, suddenly recollected himself. Such is the meaning of the expression as explained by Galen in his Commentary, and in his work *On Difficulty in Breathing*. By 'rare' is always meant 'few in number.'"

[The remainder of the demonstration related to the various editions of the Hippocratic writings and to those of commentators.]

**The History of a Forgotten Compress**.—The *Lancet* for April 2d prints the following in a letter from its Paris correspondent:

At the Société de chirurgie on March 23d the following remarkable occurrence was reported by M. Pilate, of Orleans: On April 4, 1890, abdominal section was performed on a woman, aged forty-four, for a painful fibro-myoma of the uterus. The uterus was removed with considerable difficulty, the pedicle fixed to the abdominal wound, the edges of which were then brought together. In order to protect the neighboring viscera during the operation, a certain number of sponges and gauze compresses—all carefully aseptized—were introduced into the abdominal cavity, each compress and sponge being held with a forceps. The same evening vomiting and pain came on, lasted for six days, without any elevation of temperature. A month after the operation the woman was considered cured. In the month of August, however, pain attributed to the presence of gall-stones appeared in the right hypochondrium; this disappeared in a few days. In September there was a renewal of the pains, which now involved the whole of the abdomen, and were accompanied by vomiting and tympanites, without fever. Palpation revealed the presence, in the region formerly occupied by the uterus, of a series of hard, movable nodules, resembling cancerous masses. A re-examination under the microscope of the tumor removed showed that it was a pure fibro-myoma. The patient remained in much the same condition for two months, when one day she passed *per rectum* a gauze compress enveloped in a hard fecal mass. All the unpleasant symptoms very soon subsided, and the woman has remained well since that event. This curious occurrence demonstrates the importance of counting sponges and compresses used in such operations, and furnishes one more proof of the harmlessness of foreign bodies which have been rendered thoroughly aseptic. The course of events must have been as follows: The compress, after having lain encysted must have excited an attack of peritonitis, with perforation of the intestine. That the occurrence of such a *contretemps* is not altogether unknown in the practice of the most careful surgeons is well attested. One operator now uses in abdominal sections fifteen compresses, hemmed in red, the enumeration of which is carefully made on the completion of the operation. A well-known surgeon once left a forcipressure forceps in the abdominal cavity. The instrument remained in the cavity for eight months, and was then eliminated through an abscess which formed in the umbilical region. Another relates how he once left a sponge in the abdomen, the patient dying of peritonitis three days after the operation. He no longer employs sponges.

**An Ancient Epigram and a Modern Instance.**—The *British Medical Journal* states that one of the physicians of the Glasgow Western Infirmary objects to his patients being handled on cold mornings by students having cold hands. In order to call attention to this evil, complained of anciently by Martial in his epigram to Symmachus, his physician, the Glasgow professor offered a small prize for the best translation of Martial's epigram:

Langneban; sed tu comitatus protinus ad me  
Venisti, centum, Symmache, discipulis.  
Centum me tetigere manus Aquilone gelatæ.  
Non habui febrem, Symmache; nunc habeo.

The committee has decided that two of the translations are equally good. One is by Mr. J. F. R. Gairdner, after the manner of Burns:

Smart cam' ye, sir, to me na weel,  
A hundred students at your heel;  
A hundred haums did ower me feel  
Wi' Boreas blue.  
I had nae fever then, but deil,  
I have it noo.

The other rendering, by Mr. J. F. Gemmill, reads:

I lay in number twenty-one, a case for rest and tonics,  
And good old G—— came round to me with all his train of chronics;  
A hundred meds., with fingers blue, palpated me like Lister,  
And now, no longer weak and cold, I'm frizzling like a blister.

In this connection, attention is called to Dr. Dupouy's rendering in his *Médecins et mœurs de l'ancienne Rome, d'après les poètes latins*:

J'étais dessus mon lit, couché nonchalamment;  
Le médecin Symmaque arrive incontinent.  
Les disciples nombreux, imitant son audace,  
Portent sur moi les mains plus froides que la glace,  
Et me tâtent le pouls alternativement.  
Je n'avais pas la fièvre, je l'ai maintenant.

**The Alkaloids of Aconitum Napellus.**—Two papers of unusual interest, says the *Lancet* for March 19th, were read at the last meeting of the Chemical Society, on the 3d inst., by Professor Dunstan. The first paper was a record of the research carried out jointly by Mr. Umney and Professor Dunstan on the properties of the roots of *Aconitum napellus*. For the purpose of experiment they dried the fresh roots at a low heat, and then, after powdering, exhausted them with fusel oil. The alkaloids were dissolved out of the fusel oil with weak sulphuric acid, and the acid mixture was treated with chloroform to remove resin. The liquid was next made alkaline with ammonia and shaken with ether and then with chloroform. The ethereal solution yielded a gummy residue, from which they extracted aconitine as a crystalline hydrobromide, all attempts to crystallize the residue having failed. Crystalline aconitine was successfully prepared from the hydrobromide, and it was found that the base dissolves only to the extent of 1 in 4,431 of water. The base does not appear to exist naturally in a combined state, as the juice squeezed out of the fresh root contained very little aconitine. All attempts to crystallize another alkaloid found in the ethereal liquid failed. It possesses a bitter taste, does not produce numbness, and Mr. Umney and Professor Dunstan have given it the name "napelline." The chloroform solution contained aconine,  $C_{26}H_{41}NO_{11}$ , the properties of which and its relation to aconitine formed the subject of the second paper, contributed by Professor Dunstan and Dr. F. W. Passmore. The authors showed that by heating aconitine with water in a sealed tube at  $150^{\circ}C$ , aconine and benzoic acid are formed, as originally stated by Wright and Luff. The properties of aconine have been studied; it is dextrorotatory, while its salts, like aconitine, are levorotatory. The authors made attempts to synthesize aconitine by heating aconine with ethyl benzoate, and the successful results which followed the experiments are calculated to be of the utmost importance to pharmacy and medicine. The action which takes place may be represented as follows:  $C_{26}H_{41}NO_{11}$  (aconine) +  $C_6H_5CO_2C_2H_5$  (ethyl benzoate) =  $C_{26}H_{40}(C_6H_5CO)NO_{11}$  (anhydroaconitine) +  $C_2H_5OH$  (ethyl alcohol). Anhydroaconitine so obtained forms aconitine with water. The experiment indicates that

aconitine is monobenzoyl aconine,  $C_{26}H_{40}(C_6H_5CO)NO_{11}$ . One or two derivatives were prepared—aconitine methyl iodide, for example—the physiological action of which, as well as the other new compounds, is being studied.

**The New York Academy of Medicine.**—The special order for the meeting of Thursday evening, the 21st inst., was a paper on Hydrotherapy, by Dr. W. H. Draper.

At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 27th inst., Dr. C. A. Powers will read a paper on Partial Laryngectomy, and Dr. J. E. Newcomb will read one on Syphilis of the Lingual Tonsil.

At the next meeting of the Section in Obstetrics and Gynecology, on Thursday evening, the 28th inst., Dr. H. J. Boldt will read a paper on Carcinoma Uteri, and Dr. C. A. von Ramdohr will read one on The Treatment of Puerperal Fever.

**Messrs. Reed & Carnrick's Preparations.**—In our last issue we copied an article from the *Lancet* to which we gave the heading An Appreciative Notice of American Pharmaceutical Preparations. By inadvertence we omitted the *Lancet's* heading showing that the article related to Messrs. Reed & Carnrick's preparations.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

RESULTS IN CASES OF HIP-JOINT DISEASE

TREATED BY

THE PORTABLE TRACTION SPLINT

WITHOUT IMMOBILIZATION,

EXCEPT DURING THE INFLAMMATORY STAGE OF THE DISEASE.

By LEWIS A. SAYRE, M. D.,

PROFESSOR OF ORTHOPEDIC SURGERY  
IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

In the last few years so many papers have been published on hip-joint disease, advocating absolute *immobilization* of the joint during the entire treatment of the case, and in many cases without traction, and some of them condemning the portable traction splint, which has yielded such excellent results in my hands, as well as in those of many others who have used it properly, that I have taken the trouble to look over my note-books and ascertain the results in the various cases of which I have record.

In some cases the recovery has been so perfect and complete, in reference to both form and motion, that the question has been raised whether the patients had ever been troubled with hip disease. It is on this account that I have selected only such cases to report as had been examined by other surgeons of the highest standing, and whose knowledge and ability to make a correct diagnosis would certainly be unquestioned in the professional world.

CASE I.—In August, 1877, while on a visit to London, I was requested to see J. C. O'C., an Irish boy of five years, in consultation with Mr. William Adams and Sir James Paget, who had been attending the lad, in connection with Dr. Quain, for disease of the right hip joint since April, 1877. The mother was an uncommonly healthy and vigorous woman of about thirty. The father, an unusually stout and robust man, had died of apoplexy.

The boy had fallen out of a brougham while driving on a hard road in Ireland in November, 1876, during his mother's absence, and the nurse had concealed this fact for some months. He gradually grew stiff in his gait, and then became quite lame. The lameness increased and the joint became very painful, especially at night, waking him out of a sound sleep with frequent paroxysms. The mother brought him to London to consult Dr. Quain, who called Sir James Paget and Mr. William Adams in consultation, and they all agreed in the diagnosis of *hip disease of the right side*, and confided him to Mr. Adams for treatment, Sir James Paget and Dr. Quain seeing him occasionally. Mr. Adams applied a stiff molded leather to the hip and a splint to the leg, with extension by weight and pulley, and forbade the child to walk—an imitation, or, as he said, “a modification of the American plan of treatment.”

The case not progressing favorably, Sir James Paget became dissatisfied with the American plan, and I was called in consultation in August, 1877. There was no difference of opinion as to the diagnosis. We all agreed that it was an unmistakable case of hip disease in the first stage, rapidly advancing to the second stage. There were flexion of the thigh, abduction of the limb, eversion of the toes, and perfect immobilization of the joint from muscular rigidity, and the very slightest pressure on the trochanter, or upward from the knee or heel, caused the most exquisite pain. The *slightest* attempt at movement with-

out traction was unbearable. But as soon as slight traction was made in the direction of the distorted limb, while the pelvis was held immovable, very slight motion could be made at the joint without pain.

We did not agree in the opinion as to the cause of the trouble. They were disposed to attribute it to the strumous condition of the boy, on account of the great disparity in the ages of his parents. But, as they were both in perfect health at the time of his birth, and the boy had always been in perfect health up to the time he was thrown from the brougham, I was disposed to attribute the disease to this accident, and not to any constitutional diathesis.

We also differed in our prognosis of the case. They considered recovery with ankylosis a very good result; and I contended that many patients recovered with good motion, and sometimes with little or no deformity. I was therefore requested by Mr. Adams to take charge of the case.

No change was made in the mode of extension of the leg by the weight and pulley; but I removed the leather splint from around the thigh and pelvis, and, passing a handkerchief around the upper part of the thigh, attached it to a cord, with a weight and pulley to make *lateral* traction\* from the side of the bed, and fixed the body and well limb to a long splint, thus keeping the body in a horizontal position and absolutely at rest until the acute symptoms subsided and the limb was in proper position to apply a splint.

Mr. Ernst, Mr. Adams's instrument-maker, manufactured under my supervision a very perfect long splint, which I applied to the boy in the last of August, 1877. In a very few days he was able to walk on this splint, with his sound leg elevated on a high shoe, without any pain, and could sit down with but very slight inconvenience. This splint was used by day, and the weight and pulley extension at night, the nurse having been very carefully instructed as to the proper application of the instrument as well as the night extension. He returned to his home in Ireland in September, and Dr. Hobart, of Cork, applied the Maw's moleskin adhesive strips about every three months, or as often as necessary.

This long splint was worn for eleven months, when he had so far improved that my short hip splint, with double perinea bands, was substituted for it. With this short splint he was able to get about very much more comfortably, particularly in sitting down, as it gave full power to flex his knees, the lack of which is one of the objections to the long splint. He wore this splint about a year, and when I removed it, in the fall of 1879, he was perfectly well of the disease, with no perceptible deformity and quite free motion of the joint. The limbs were of equal length, but the right one was much atrophied from want of use.

He had a very competent nurse, who gave the limb massage and manipulation daily, carefully increasing the range of motion without exciting fresh inflammation, and in a few months the motions were as perfect in one joint as in the other, and have continued so. He was under treatment a little over two years. He is now nineteen years old, in perfect health, can run, jump, and undergo severe military drill for many hours as well as the average. He is perfect in form, can flex the thigh to an acute angle, and cross the foot over the thigh of the opposite side, as

\* As there has been considerable discussion as to priority in the application of lateral traction in hip-joint disease, I may say that on looking over my notes I find that I applied it to L. A. McC. in 1868 in the presence of Dr. L. M. Yale, this being the case to which I first applied a platform joint with abducting screw with a short splint, the original drawing of which, by Dr. Yale, I found in my note-book.

seen by the photographs. This last motion is very difficult to accomplish if there is the least rigidity about the hip joint. Most patients having recovered from hip disease, even with quite good motion of the joint and with but a very slight limp, yet can not cross the foot to the opposite side to tie their shoes, but always put their foot to the side and behind them in order to get at their foot. I therefore look upon this test as the best proof of perfect motion in the joint.

CASE II.—J. McC., aged four years, daughter of A. McC., Troy, N. Y., was sent to me in July, 1864, by Dr. Brinsmaid and Dr. Thorn, who had been attending her for six months for a very painful trouble of her right hip, which was supposed to be rheumatic. As she made no improvement, Dr. Alden March, of Albany, was called in consultation and diagnosed hip disease in the second stage, rapidly progressing, and with very great constitutional disturbance. Dr. March thought the disease due to a fall the child had received the winter previous, and advised them to send her to me for treatment.

I saw her on the 9th of July, 1864, at the St. Nicholas Hotel in this city. She was rather small for her age, very pale and anæmic, exceedingly irritable, and almost all the time crying from pain when she was not under the influence of an anodyne, which had to be repeated frequently, especially at night. The limb was flexed forty-five degrees, abducted, and strongly rotated outward, with the toes everted. There was some fullness over the hip joint, which was exceedingly sensitive to the slightest touch, and the least pressure on it in any direction caused her to scream in agony, as did also the slightest attempt at motion when made without traction or extension. When, however, the pelvis was held still by an assistant and the limb was seized firmly, and slightly flexed, abducted, and rotated outward, then slight traction on the limb while held in this position gave her perfect relief from all pain, and she seemed happy. The instant the traction was removed she screamed in agony, and was only relieved by a repetition of the traction in the same line as at first applied while the pelvis was held still and free from movement.

*Diagnosis.*—Hip disease, second stage.

*Treatment.*—Extension in the line of the deformity, the line of traction to be daily changed until the limb was in normal position, then apply a short hip splint for daily exercise, and extension by weight and pulley at night. In the mean time to apply a blister 2 × 4 inches behind the trochanter, to be repeated if necessary. Messrs. Otto & Reynders measured her for my short hip splint, which they said was the smallest one they had ever made. I applied adhesive strips from the ankle to two inches above the knee, and secured them by a firmly applied flannel roller. To the lower ends buckles were attached for the purpose of making extension. The whole limb was raised on a pillow and slightly abducted; the body was also propped up by a chair behind the back to relax the psoas and iliacus muscles, the foot of the bed being elevated and a four-pound weight attached. In less than an hour the child was in a sound sleep, which the parents said had not occurred before for many months without an anodyne. The blister had a beautiful serous discharge in about seven hours, and dried up in about two days. It was repeated twice in the course of the next ten days. The line of traction was gradually changed, and in two weeks the leg was parallel with the other. I then applied my short hip splint with the single perineal band for counter-extension, and she was perfectly comfortable. The following day she was able to sit up in a chair, and after some little instruction was able to walk around the room on her crutches quite comfortably.

She returned to Troy that night by the steamboat, and as it

was difficult for them to apply the night extension by weight and pulley in the berth on the steamer, I advised them not to remove the splint for that night, but allow her to sleep in it, which was done, and "she arrived at home the following day without any pain or inconvenience," as stated in a letter to me from Dr. Brinsmaid a few days after.

I received letters from Dr. Brinsmaid every few weeks during the summer and fall, stating that she was entirely free from pain and growing very rapidly; that he "had no occasion to change the plasters, as the splint was retained in position as I had left it, and that he increased the extension as the limb grew longer by keying out the splint a notch or two every few weeks as the case required."

In February, 1865, while attending the meeting of the State Medical Society in Albany, Dr. Alden Marsh and myself were invited to dine with Mr. McC. in Troy, and to see the great improvement that had taken place in his daughter's hip. Dr. Brinsmaid, of Troy, was also present at the dinner. We found the little girl running around the room with her crutches, in perfect health, and in very good shape; but when we stripped her for examination I was very much surprised to find the splint and bandages exactly as I had applied them in July, 1864, nearly seven months before, the splint having never been removed during all that time, and the night extension by weight and pulley had never been applied. The extension had been kept up by keying out the splint occasionally, and as the adhesive plasters had remained *in situ*, as I had originally placed them, the traction was perfect.

Dr. Brinsmaid explained that the reason of his leaving on the splint at night was the fact that she had slept so comfortably with it on in the boat on her way home that he was afraid to remove it, fearing that he might not again be able to replace it in exactly the same position, and, as she had suffered so many months of intense pain before, and was so perfectly comfortable since it had been applied, he preferred to leave it, merely covering over the soiled bandages with a clean roller as occasion required, but never disturbing the original bandage or adhesive plaster.

This was to me an entirely new revelation, but, as she was so perfectly comfortable, I advised them to continue the same plan, but to send her to me as soon as I returned to the city, that I might make a new application of fresh plaster.

She was sent to the city on the 1st of March, 1865, and I removed the dressings, which, of course, were very much soiled; but the plasters were in exactly the position as originally applied in the preceding July, and, on carefully removing them, the scarf-skin came off with them, but left no abraded surface underneath. As the skin was not in a fit condition for the immediate application of the plaster again, I put her to bed with an extension from her foot for a few days until the skin, by the daily washing with alcohol, should be in proper condition for the reapplication of the Maw's adhesive plaster for the extension splint. On the 4th of March, 1865, the adhesive plasters, bandage, and splint were applied as in the first instance, and she returned to Troy. She wore this splint constantly, day and night, for two years and a half, and was then perfectly well. She had returned to the city four times during that period to have the plasters removed, and there was never any abrasion of the skin.

I saw her mother at the Mizzen Top Hotel, in Putnam County, in September, 1890, and she stated that her daughter was in perfect health, married, and had two children. Her form was perfect, the limbs were of equal length, and she had perfect motion of every joint.

CASE III.—D. E., son of one of New York's most distinguished physicians, both of whose parents were perfectly

healthy, fell in 1869, when he was six years old, from a trapeze in Wood's Gymnasium, striking on the wooden floor on his left hip and thigh, and driving a splinter of wood into the outside of the left thigh just below the trochanter major. This splinter of wood was cut out by Dr. George A. Peters the same afternoon, and the wound healed kindly in a short time.

Some two months after this accident he began to limp, and walked so stiffly and awkwardly that he was taken to Dr. Valentine Mott, who advised him to be put to bed, with a stimulating liniment applied to the joint. In a few weeks he seemed so much better that he got up and walked very comfortably, but, going down stairs, caught his left foot in the banister and fell down a flight of twelve steps, striking on the marble hall floor on the same left hip that had been previously hurt. Having disobeyed the orders of Dr. Mott as to perfect rest in bed, they did not inform him of this last accident, thinking that the trouble would soon subside by rest again in bed. But at the end of three weeks he had grown so much worse that Dr. Mott was called again to see him, and, finding him so much worse than at his last visit, some two months before, he called Dr. W. H. Van Buren in consultation, who at once diagnosticated it as a case of hip disease, and advised to have me see him. I saw him in consultation with Dr. Mott and Dr. Van Buren, and found him with the left thigh flexed, abducted, toes everted, and hip apparently ankylosed from muscular rigidity. The least attempt at movement without traction caused the most exquisite pain, as did pressure on the joint from any direction. Very slight traction, with flexion and eversion, relieved the pain, and permitted the slightest movement of the joint when the pelvis was held immovable.

*Diagnosis.*—Hip disease, second stage, with effusion in the joint, in which opinion we all agreed. Dr. Van Buren requested that I should take charge of the case, to which Dr. Mott cheerfully consented.

I placed him in bed with the foot elevated, applied a long splint to the right side of the body and leg, and applied adhesive plaster with weight-and-pulley extension to the left leg, and also applied traction from the upper and inner portion of the thigh by a weight and pulley at the side of the bed. A blister 4 × 4 inches behind the trochanter was applied. A pillow was placed under the thigh and leg to accommodate the flexion of the limb, and the thickness of this support was gradually reduced as the limb became straighter, and in a few days it was down in the bed and parallel with the other limb. The blister had a very decided influence on the effusion in the joint, and was repeated three times in the course of a few weeks.

From the moment that the double traction was applied to the limb his pain was entirely relieved. No sedatives of any kind were used from this time, although he had been compelled to resort to them every night for some time previous to the application of the traction. He was kept rigidly in this horizontal position, with the traction, for a little over three months, when he was so much improved that I then applied to him my short hip splint, with which and a pair of crutches he was able to walk about during the day, while the extension was continued at night by the weight and pulley. The splint was reapplied every few months as the plaster became loose, and was worn for nearly two years, when he was entirely cured, and had quite good motion of the joint, the limb was considerably atrophied, but apparently of equal length with the other.

The motions gradually increased with exercise and the limb developed until it became in time as large as the other, and he was the champion athlete of Columbia College, having won a mile-and-a-quarter run in 1879. He is now perfect, as seen in photograph.

CASE IV.—In December, 1864, I was requested to meet Dr.

Naudain, of Westchester, in consultation with Dr. Valentine Mott, to examine the youngest son of Mr. G. M., of Morrisania. He was a lad of four years and six months, rather delicate in appearance, and apparently suffering great pain on the least movement in any direction, but more especially if any movement was made of his right lower extremity, which was slightly drawn up and abducted, but rigidly fixed by muscular contraction. There seemed to be some fullness around the hip joint, but no distinct fluctuation could be detected. The least pressure or motion of the joint caused him to scream violently; but when the pelvis was held, and slight traction made on the limb in the line of flexion and abduction, he was almost immediately relieved.

The boy's father was very vigorous and robust, but suffered from rheumatism and gout. The mother was very delicate and suffering from phthisis, from which she eventually died.

The boy, although delicately built, had always been very active and venturesome. In the early spring of 1864 he had climbed upon the stone wall of the garden to pick some lilac flowers, and in breaking off the branch had lost his balance and fallen about four or five feet into a pile of stones. He cried very bitterly for some time, but the next day seemed as well as ever, and the accident was forgotten. After a few weeks the mother noticed that he was a little stiff in the morning and favored one leg when standing, but in a few hours he would run about as before without any complaint of pain, and she therefore attributed it to "growing pains" and gave no attention to it until later in the fall, when his lameness became so much worse that Dr. Naudain was again called to see him.

As the father was a martyr to rheumatism and gout, the doctor thought the boy had inherited the diathesis, and treated him accordingly. But after some weeks, as he did not improve, Dr. Mott was called in consultation and diagnosticated the case as one of hip disease, and advised them to place him under my treatment.

I saw him the following day in consultation with Dr. Mott and Dr. Naudain, with the symptoms already described in this paper, and of course confirmed the diagnosis of Dr. Mott. I applied traction to his limb in the line of the deformity by means of adhesive plaster and weight and pulley, and also lateral traction from the upper part of his thigh by a handkerchief around the limb attached to a weight by the side of the bed, and applied a blister 2 × 2 inches behind the trochanter.

As soon as the traction was properly adjusted he fell asleep without any opiate, which the mother said he had not done for some months. He was kept in his bed a little over two months, Dr. Naudain changing the line of traction as required, until his limb was perfectly straight at the pelvis and parallel with the other. I then applied my short hip splint, and in a few days he could walk with the aid of crutches very well. At night the splint was removed, and the extension applied by weight and pulley. The splint was reapplied every few months, as the adhesive plaster became loose, and was worn constantly, except at night, for a little over two years. At the end of two years and a half he was perfectly well, and had quite free motion of his joint. This gradually increased until it became perfect, and has remained so.

Some two years ago, when I first thought of preparing this paper for the meeting of the Orthopædic Society in Philadelphia, I wrote to him to send me his photograph in the different positions I have described, in order to illustrate the perfect motion of the joint. I received no reply, and was then taken very ill, and the paper was not completed. Some months after I received the following letter, and in a few days the accompanying photographs.

GLENWOOD SPRINGS, COLORADO, *September 9, 1890.*

MY DEAR DOCTOR: Your letter was delayed some time in reaching me by being misdirected, and consequently going to the Dead-letter Office.

I have had photographs taken as you wished, and they will be sent you by the photographer. I had to have each position taken right and left, for I do not know which leg was injured. I do not know just how old I was, nor what kind of splint or brace I wore. I am very well and athletic, riding on bucking horses, and using all my limbs and muscles with absolute ease and comfort.

Hoping the photographs will be satisfactory, and with much love, I am  
Your grateful friend,  
R. M.

I saw him in January, 1892, on his way to Europe, and he was perfect in form and motion.

CASE V.—L. H., aged thirteen, Buffalo, N. Y. Father and mother apparently healthy; an aunt died of phthisis, and grandmother had Pott's disease. She was brought to me on April 17, 1886, by Dr. Jewett, of Buffalo. Menstruation began at eleven, has always been rather profuse, and the patient is now quite anæmic.

In November, 1885, complained of great pain in right hip. Shortly before that her cousin had given her a severe twist by catching her around the neck and pulling her backward. For some time after this she complained of great pain in her back. For the past two months has had nocturnal startings. Six weeks ago was put to bed, and had blisters applied over and behind the trochanter, but no extension. Dr. Kirtland, of Utica, and Dr. F. B. Johnson, of Towanda, then saw her in consultation with Dr. Jewett, and they all diagnosed hip disease of the right side, with probably sacro-iliac disease of the same side.

She was brought to the city, and I saw her in consultation with Dr. Jewett on April 17, 1886. Very limited motion of right hip from muscular rigidity; great pain on compression, both longitudinally and laterally; also great pain over the right sacro-iliac junction, and pain on lateral pressure of the ilia, and the body strongly bearing to the *left*; thigh flexed, abducted, and fixed by muscular rigidity, and the toes everted.

*Diagnosis.*—Hip disease, right side, second stage, and sacro-iliac disease of right side.

*Treatment.*—Put to bed, with weight-and-pulley extension to reduce the limb to the normal position. From this time all night spasms ceased, and she slept quietly without any narcotic, although she had been compelled to resort to them once or twice every night for some weeks before.

*May 17, 1886.*—The limbs had become so nearly parallel that the long hip splint was applied, and, by the aid of crutches and a high shoe on the left side, she was able to walk quite comfortably, and went back to Buffalo.

*October 4th.*—Returned, very anæmic from profuse menorrhagia. Tenderness over the trochanter and just above; deep fluctuation posterior to the trochanter.

*10th.*—Put on new adhesive plaster, and applied the actual cautery over the tender spot on the trochanter, and also over the sacro-iliac junction on right side, which was tender.

*December 10th.*—Wounds from actual cautery entirely well. The abscess which seemed to be forming above and behind the trochanter has disappeared, and no fluctuation can be felt.

*January, 1887.*—The hip is much less tender; opened the knee joint in splint to allow the knee to be bent while sitting.

*November.*—Very greatly improved; is free from all pain; can flex, extend, adduct, abduct, and rotate the leg almost as perfectly as the other. Removed the plasters from the leg and applied the splint, with a box in the sole of the shoe and flexion at knee joint when sitting

This was worn until August, 1888, when she was found to be perfectly well, and all treatment was abandoned. The limb was very nearly of the same length as the other, but not so large in circumference. The motions in the joint were almost perfect and complete.

*June, 1890.*—Is in perfect health, and has no difficulty in performing any motion of the joint, as seen by photographs taken by Dr. Reginald H. Sayre, January, 1890.

CASE VI.—F. N., aged nineteen years, 18 West Twenty-eighth Street. On October 21, 1872, I was requested by Dr. Barker to see Mr. F. N., aged nineteen, who had been sent home from Harvard University by Dr. Bigelow, of Boston, on account of his suffering from hip disease, which prevented him from attending to his college duties. I fully confirmed the opinion of Dr. Bigelow, which greatly disturbed his mother, as she could not believe that he could have any such serious trouble, because he had always been so strong and healthy, and she did not like him to give up his college course, and she therefore wished Dr. Van Buren to be called in consultation, hoping that he might differ with Dr. Bigelow and myself.

Dr. Van Buren saw him with Dr. Barker and myself on the 22d of October, 1872, and, after a most careful examination, pronounced it hip disease, first stage, far advanced toward second stage. The limb was *apparently* longer, flexed, abducted, and rotated outward, and firmly fixed by muscular rigidity, apparently ankylosed. The slightest pressure on, or the least motion of, the joint caused intense pain and made him cry severely.

In the early spring of that year, while running across country at Lenox, he had slipped one foot into a deep ditch, while the other leg was stretched out sideways on the ground. He was considerably hurt, and kept his bed for two weeks, at the end of which time he thought himself well, yet there remained a slight pain, which, in fact, never entirely disappeared. In August he again hurt his hip in Newport, slipping on the grass, which confined him to his bed about ten days. He afterward went to Harvard, and in getting off a horse-car slipped, hurting his hip very badly.

Dr. Bigelow, of Boston, was then called to see him, and after attending him some weeks told him he had confirmed chronic hip disease and advised him to return home.

After Dr. Van Buren had confirmed the diagnosis of Dr. Bigelow and myself, he was placed by Dr. Barker under my treatment. I applied the extension by weight and pulley on October 29, 1872, with a blister 3 × 4 inches behind the trochanter. This was repeated three times during the next two months, during which time he remained constantly in bed.

*December 24, 1872.*—Applied my long hip splint and put a high shoe on his sound foot, and by the aid of crutches he could walk quite comfortably. The plasters were reapplied every few months as occasion required until the first of May, 1874, when the splint was removed and has not again been applied.

The motions of the joint were limited at the time, but by daily massage and manipulation they gradually increased, and in a few months were as perfect as in the other limb, and have remained so. His limbs are of equal length, and every motion of the joint is perfect, as seen in these various photographs taken by my son, Dr. Reginald H. Sayre, March 8, 1892.

CASE VII.—S. C. H., aged seven years; healthy parents and family. Child an unusually fine boy up to October, 1873, when he had a fall while jumping about on the floor; cried a good deal from the injury, saying his hip was hurt. In a few days after, a very severe attack of scarlet fever prostrated him, a large abscess under left jaw formed, and was opened. Convalescence was quite slow. After the abscess of the neck ceased to discharge

he complained of his left hip and knee. Was treated for rheumatism for some time, and then by weight and pulley *incorrectly* applied. I found him, December 1, 1873, confined to bed in a very feeble state, and applied weight and pulley *correctly* by *simply modifying the line of traction*, which gave instant relief. On January 10, 1874, he was brought before the class at Bellevue and my short hip splint applied.

January 22d.—Boy up, feeling much relieved. Not confined to bed a day since the splint was applied.

February 20th.—Splint readjusted to-day. Boy in most excellent condition. No pain or tenderness on manipulating the joint; walks readily with no crutch. Has not suffered a day since the splint was applied.

January 3, 1875.—Perfectly well, with no deformity, and all the motions of the joint quite free and normal.

January 22, 1886.—Mr. H. called on me to present his splint and crutches for some other ease. He is in perfect health, five feet six inches in height, weight one hundred and thirty pounds. Has every motion of the hip joint as perfect as the other. Can ride horseback and do full labor. The left limb is half an inch shorter than the right, and the thigh three fourths of an inch smaller than the other, but this defect can not be detected without careful measurement. Cure perfect.

February 19, 1890.—Mr. H. called to-day to ask whether it would be advisable to join a bicycle club. Has ridden at different times, but not steadily. More careful examination shows that motion was limited in outward rotation. Can cross the knees, but can not put the foot on the other knee and drop the knee to right angle. Abduction also limited. He was advised not to try the bicycle riding.

I am very glad this patient is here this evening, that I may show the difference between what I call a *perfect* cure, as in the case of Mr. E., and a *good* cure, as in the present instance.

I had recorded the case as a perfect cure, as he could flex and extend the hip joint, cross his knees, and walk without limping with an elevated sole, but, on later examination, find that he can not put the left foot in his lap, and I have therefore included him in the list of good instead of perfect cures.

In the cases which I have reported in full this evening the patients had undoubted morbus coxarius, as diagnosed by surgeons of marked ability, in addition to my own testimony, and yet they have all recovered with useful, movable hip joints, as seen this evening, in spite of the fact that several of them were of tubercular families, and prove the fact that absolute immobilization during the entire progress of the disease is not always essential to perfect recovery.

I have had my note-books looked over by Dr. H. W. Frauenthal and Dr. B. F. Parish, who have kindly prepared a synopsis of the cases therein recorded, and to whom I wish to return my thanks for their arduous labors.

I wish the time at my disposal had been sufficiently long to render the table more complete by recording the cases complicated by abscesses and those complicated by disease of other joints, but, as the chairman had requested the paper for this meeting, I have gathered together such facts as I could in the time at my disposal, and hope at some future time to present these statistics more fully elaborated.

Many of the cases on my books have been seen by me only once or twice in consultation with other physicians, and

these have not been included in the record; and in other cases it has not been possible to ascertain the ultimate result; but the cases as recorded in my books I have collected and here present to you. The cases in which excision of the hip joint was practiced have not been included, as they have already been published, and many of these were not in a condition to allow anything short of radical operations at the time when I first saw them.

*Statistics of 407 Cases of Morbus Coxarius treated between 1859 and 1889, exclusive of Excisions.*

Of these there were in the

I have had no personal experience in the treatment of hip disease by perfect immobilization, but had to exsect in one case in which the joint had been *immobilized* by a plaster-of-Paris cast from axilla to foot for *two* years. The first cast being applied in the very early stage of the disease, the limb was retained perfectly straight by the plaster casting; but as *no traction* was used, the reflex muscular action caused constant pressure of the head of the femur against the acetabulum, causing absorption of the head of the femur and perforation of the acetabulum. An abscess forming inside of the pelvis peeled off the periosteum and opened above Poupert's ligament. As there was not the usual deformity of hip disease, and no pain on upward pressure of the limb, the surgeons in attendance did not recognize it as hip disease, and I was called in consultation. I gave as my opinion that the joint was already destroyed, and that *exsection* was the only chance for saving the child's life.

Dr. Kraekowizer was then called in consultation to decide the question, and, confirming my diagnosis, I exsected the joint in the presence of Dr. S. Sabine, Dr. Kraekowizer, Dr. Yale, Dr. Markoe, and others. The head and neck of the femur were absorbed and the acetabulum perforated.

The operation was a success, and, eight months after, I saw the boy riding on horseback in the mountains of Virginia.

He went back to Texas, and two years after was attacked with nephritis and died from suppuration of the kidney.

In 1859 I was requested to go to Frankfort, Ky., to see a young lad suffering from hip disease of three years' standing. As I could not leave the city at the time, I requested my friend Dr. Baur, then of Brooklyn, to go in my place. The doctor divided the contracted muscles, straightened the limb under chloroform, and placed the boy in the wire breeches, which made him perfectly comfortable. In fact, he was so comfortable that Dr. Rodman, his attending physician, was afraid to remove him from the wire breeches, fearing that he would not again be able to replace him as comfortably as he then was.

He was carried down on the Kentucky River every day for a row, and was perfectly free from pain from the time that Dr. Baur placed him in the cuirass. He was not removed from the wire breeches for nine months, and when he was taken out the disease was perfectly cured, but the joint completely ankylosed, as were also the hip of the opposite side, both knees, and both ankles, as well as the entire lower portion of the spine. In fact, he could only move his arms and neck. He remained in this solidified condition till his death some years later.

In 1872 a girl was brought to me from Hamilton Junction, New Jersey, with *double* hip disease of eighteen months' standing. The right, third stage; the left, probably the same. After gradually straightening the limbs, she was placed in the wire cuirass.

The limbs were removed from the cuirass occasionally,

and slight motion was given to all the joints, while the limb was kept extended by traction with the hand.

Her general health improved greatly, and in six months she returned home in the cuirass, the mother having been carefully instructed as to the manipulation and dressing of the limbs. I received a letter from the mother in the latter part of 1873, saying that "she had entirely recovered, with good motion of both legs and no deformity."

Four years later, in March, 1877, the father called on me and said that "Mary was entirely well and very stout, but that the joints were stiff," as he found it too much trouble to take her out of the splint so often, but that he was perfectly delighted and satisfied with the result. I was not. My impression is that, had the limbs been occasionally removed from the cuirass and the joints slightly moved short of the amount that caused pain, this ankylosis would not have taken place.

## MORVAN'S DISEASE.

By B. SACHS, M. D.,

PROFESSOR OF MENTAL AND NERVOUS DISEASES,

AND S. T. ARMSTRONG, M. D., PH. D.,

INSTRUCTOR IN MENTAL AND NERVOUS DISEASES, NEW YORK POLYCLINIC.

IN 1883 Dr. Morvan, residing in a little town in Brittany, published a paper on a disease that he had observed there to which he gave the name of analgesic paresis and panaritium of the superior extremities, or pareso-analgesia. In this paper he stated that at the commencement the disease was limited to one extremity, subsequently passing to the other, and always terminating in the production of one or more felons.

In the cases as first described by Morvan the symptoms are initiated by a weakness of the muscles, and sometimes by a pain in the forearm, that is succeeded by a swelling of the member, with the formation of deep palmar fissures and felons, usually painless, with phalangeal necrosis. It was for the latter condition that the physician was consulted, and at that period there was usually paresis of the muscles of the affected region that was afterward followed by atrophy of the thenar, hypothenar, and interosseous muscles. While faradization would produce energetic contractions in the muscles of the forearm, no reaction would be obtained in the atrophied muscles. There was analgesia of the forearm, sometimes of the arm, neck, and chest; and also thermal, but no other anesthesia. Exertion produced occasionally hyperidrosis of the analgesic region; and the existence of vaso-motor disturbance was further evidenced by the bluish or mottled discoloration of the affected part in cold weather, and the occasional formation of phlyctenulae. Of his reported cases, seven were in males and two in females, and the disease had lasted from a few to twenty-five years without involvement of other regions.

It seems to us that the report that Morvan made of what seemed to him to be a new disease should be considered in giving it a place in nosology. The existence of paresis, loss of pain sense and thermal sense, circumscribed atrophy of the forearm or hand muscles, and trophic disturbances evidenced by the formation of cutaneous fissures

and felons, would constitute what is known as Morvan's disease. In all reported cases of the disease made at a subsequent date these have been the essential symptoms, and the following case is added to the literature of the subject, the patient having been presented for examination to two medical societies of this city :

W. H., aged twenty-eight, a native of Germany, a laborer, was referred to Dr. Sachs's clinic at the New York Polyclinic by Dr. Gerster. The patient had a venereal ulcer and a bubo in the right groin ten years ago, but otherwise he has always been healthy until four years ago, when he was employed as a dish-washer, his hands lost their muscular power, there was slight twitching and enlargement of the fingers, and the skin of the fingers and hands became thickened and fissured. He was treated by a physician, and the enlargement in the fingers subsided, except in the index and third finger of the left hand, in which felons formed, that were incised without causing any pain. He thought that the condition of his hands resulted from the use of soda in the wash-water; but it is now four years since he stopped washing dishes, and his hands have not improved. At the time of examination the skin of each hand was of a purplish color, that was intensified by cold weather, the discoloration under such influence extending up the arm. The hands themselves presented the following appearance :

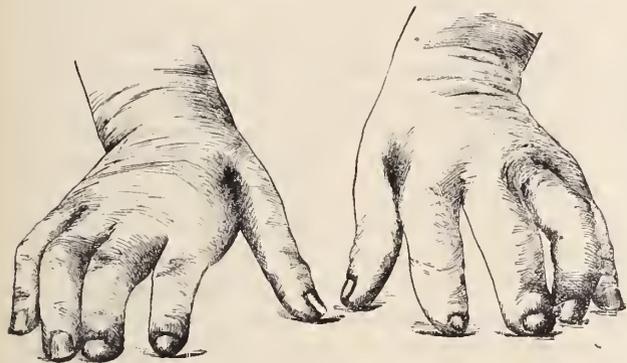

FIG. 1.

Right. The skin on the dorsum seems to be normal, but on the dorsum of the fingers it is thickened; there is a slight contracture at the second phalangeal joint in all of the fingers, but more pronounced in the middle and index fingers. There is a small eschar on the dorsum of the thumb, but this member is not contracted. There is a marked atrophy of the first dorsal interosseous muscle. On the palmar surface the skin is thickened, and there are numerous ragged excoriations, especially on the finger-tips and at the base of the middle and ring fingers; in these excoriations deep fissures, having indurated edges, have formed. On the anterior surface of the right forearm is an area of dermatitis resembling a mild degree of ichthyosis. At the bend of the elbow there is an area four inches long by an inch wide, in which there are numerous small depressed atrophic areas that might be described as a *dermatophthia circumscripta albida*; the patient thought that this had resulted from carrying a basket on his arm, the markings resembling somewhat those that would be produced by the pressure of the twisted willow in the handle thereof. There is a scar over the olecranon, caused by an incision (painful) for an abscess in 1890. Left hand: The skin on the dorsum and palmar surfaces of the hand and fingers presents a similar appearance to that of the right hand, but the nails of the index and middle fingers are thickened and deformed, and the end of the index finger is conical while that of the middle finger is clubbed. The nail of

the latter finger presents white opaque striæ, and a portion was examined microscopically to see if these striæ were caused by a mycelial growth; but no fungus was found. There is moderate atrophy of first dorsal interosseous. Dynamometer showed: *Manus dextra*, thirty kilogrammes; *manus sinistra*, sixty kilogrammes; but this disparity has been lessened during the course of the electrical treatment, and the muscular power is almost equal at the time of writing this report, though it is yet less than that of a healthy man. The muscular sense was normal, and, excepting in those muscles above mentioned, no atrophy was apparent. The forearms were well developed and were equal in circumference. The tactile and pressure senses were normal, the patient locating a straw drawn over the skin, and discriminating between different weights. The pain sense is abolished in an area on the dorsum of the right hand; also over the dorsum of the fingers, hand, and ulnar side of the left forearm; but there is no loss of pain sense in the palms or the anterior surface of either forearm. Fig. 2 shows the analgesic areas on the hands; the test was made by forcing a needle into the flesh. The temperature sense did not recognize a temperature of 212° F. on either forearm, excepting at the flexure of the elbow, where it felt hot; but at this point a temperature of 150° F. felt cold. Temperatures of 190° to 200° F. were recognized as warm on the upper portion of the arms and back, though lower temperatures were called cold. In the regions above mentioned a temperature of 32° F. was not recognized as very cold, even if it was placed on a spot on which a temperature of 212° F. had just been placed. These observations were made with test tubes containing boiling water and a freezing mixture. There is fibrillary twitching of the muscles of the forearm and hand. Fig. 1 shows the atrophy of the inter-

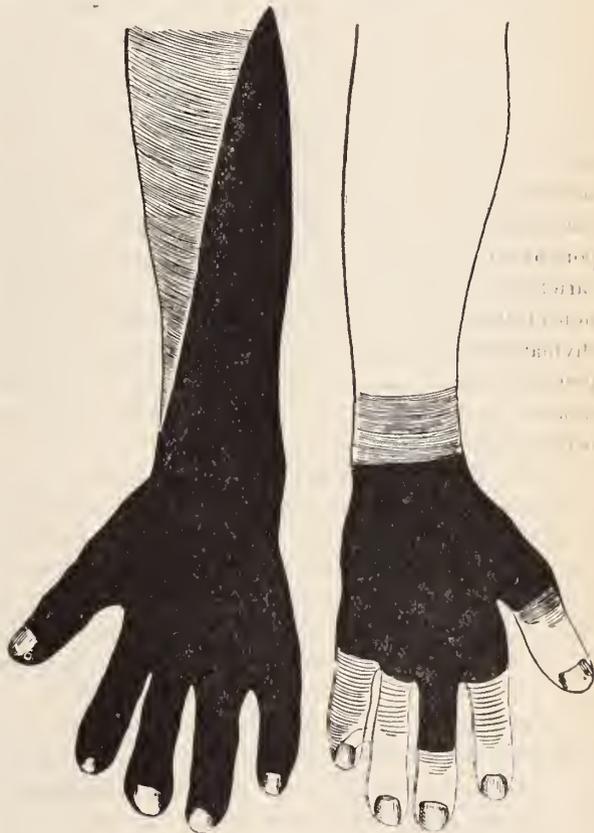

FIG. 2.

osse, the deformity of the fingers of the left hand, and the slight tendency to the *main en griffe*. An electrical examination showed an absence of the faradaic reactions in the extensor,

thenar, and interossei muscles, though the flexor group reacted well. Galvanic reactions, ACC > KCC in the extensor muscles of each forearm and the interossei. It might be here stated that since the treatment by electricity has been commenced, the faradaic reactions have returned in the extensor groups and the difference in the galvanic reactions is diminishing.

There is no history of pain in the forearms preceding the appearance of the other symptoms; his attention was first called to his hands by the fact that, when immersed in hot water, he had no sensation of its heat—a phenomenon associated with the swelling and inability to use his hands. When his entire skin is perspiring his forearms will be cold. He has had to give up positions as a waiter because he has been unable to firmly hold articles of glass or crockery in his hands.

In this case we have paresis of the muscles of the hand; analgesia of certain regions of the dorsum of the hands and of the posterior aspect of one forearm; thermal anaesthesia of both forearms, and felons on one hand—the congeries of symptoms constituting Morvan's disease.

The pathology of the disease, and, in fact, whether there was any such morbid entity as this disease, has been questioned. Osler (2) considers it a peripheral neuritis of toxic origin, and Gowers (3) considers it a peripheral neuritis with myelosyringosis.\* This theory that the disease is a peripheral neuritis seems to be verified by an examination of Morvan's first reported cases; his first case is one of traumatic neuritis following a fall, with persistent motor and sensory paresis for ten years; his second case presented symptoms of multiple neuritis, in which the affection of the nerves of the lower extremity disappeared in the course of years, certainly a result that would never have occurred in myelosyringosis; his third case seems to be one of chronic neuritis, as is evidenced by the occurrence of painful paroxysms during twenty-four years; his fifth case resembles traumatic neuritis; and his seventh case resembles one of multiple neuritis. Monod and Reboul, in their report of a case of the disease, took the position that it was a variety of peripheral neuritis, having found in an examination of the nerves of an amputated finger an acute parenchymatous and interstitial neuritis. Déjérine (13) thought that the frequent appearance of the disease in the population of a small province showed that it was a neuritis of toxic or infectious origin.

Surgical pathology teaches us that felons do not originate spontaneously, but in consequence of the introduction of the *Streptococcus pyogenes*; and the fact that the felons are usually painless seems to show that the micro-organism gains access to the tissues in consequence of the trophic disturbances, and that the felons are merely an incident that might be prevented in such cases by due attention to cleanliness.

The dissociation of sensory symptoms is the chief argument against the theory that Morvan's disease is due to peripheral neuritis, but there is evidence that all sensations are not equally affected in neuritis, as has been asserted by

Starr (5); and possibly the paucity of such records is due to failure to make special tests.

As it is a physiological fact that the conduction channels of the tactile, pain, and thermal senses lie in different parts of the spinal cord, it seems a justifiable assumption that their peripheral terminations are also different. And that recorded cases justify this assumption is evidenced by the cases of Weir Mitchell (6), in which there was a lessened sense of pain with no loss of touch; those of Gowers, in which he has seen loss of pain sense while the muscular sense is preserved; and those of Grainger Stewart (7), in one of which the thermal sense was diminished while the pain and muscular senses were normal, and in another the thermal and pain senses were diminished and the muscular sense was normal. The latter case is especially serviceable in supporting the possibility of the existence of such phenomena in neuritis, because the necropsy showed that in the median, ulnar, and tibial nerves certain "bundles of nerve fibers were totally, others partially destroyed, while some were comparatively healthy"; and in the cervical enlargement of the spinal cord there were tracts of secondary degeneration, affecting only the columns of Goll and the outermost part of the lateral columns.

These cord degenerations were in consequence of an ascending neuritis, and an explanation of the gliomatosis of the cord, in cases of Morvan's disease, is possible on the ground that there was an ascending neuritis of the sensory fibers, with later slow gliomatous degeneration in their tracts in the spinal cord. Gombault (8) found in a necropsy, in a patient who had Morvan's disease for forty-four years, intense changes in the peripheral nerves, with a mild degree of sclerosis of the posterior horns and columns. These facts justify the statement of Gowers regarding this disease, that "we must be cautious in inferring that the pathological state is the same in origin in all cases." But physiological, pathological, and clinical data support the idea that a peripheral neuritis may be the cause of the disease, though Morvan himself considers it is of spinal origin.

Myelosyringosis so closely resembles Morvan's disease in its early stages that several prominent neurologists—such as Bernhardt, Jolly, and Charcot—have considered them identical; and the latter proposed that the congeries of symptoms constituting the former disease should be denominated myelosyringosis of Morvan's type. Now, myelosyringosis is a purely pathological condition that may include, according to Cheron (10), first, dilatation of the central canal, or myelohydrocyst; second, the excavating myelitis of Joffroy and Charcot; third, the peri-ependymal sclerosis of Hallopeau; and, fourth, gliomatosis of the region of the central canal. And with these various pathological conditions Joffroy and Achard concluded (11), from a study of the disease in general, that often a sufficient number of the supposedly pathognomonic signs are not present to allow a diagnosis to be made; again, that where all of these signs are present they may suddenly disappear, and a spontaneous recovery is hardly to be expected in such a disease—in other words, a peripheral neuritis has been mistaken for myelosyringosis. In the following table we present a comparison of the essential features of both diseases:

\* Our attention has been called to the barbarism in the composition of syringomyelia, and we have adopted myelosyringosis as a term that avoids the etymological error in the more usual word.

<i>Myelosyringosis.</i>	<i>Morvan's Disease.</i>
Felons rarely present, and only as a symptom of a trophic disturbance.	Formation of painless felons.
Fissures rare.	Palmar cutaneous fissures.
Analgesia of areas supplied by the segment of the affected cord; usually arms and upper half of trunk; rarer in lower part of trunk and legs.	Analgesia of fingers, of hand, and forearm; later and rarely of arm and neck.
Thermal anæsthesia of analgesic and other regions; sometimes unequal for heat and cold, sometimes perverted.	Thermal anæsthesia extending moderately beyond the analgesic areas.
Muscular atrophy of region supplied by nerves emerging at or immediately below the level of the affected segment of the cord.	Muscular atrophy usually limited to thenar, hypothenar, and interosseous regions; more rarely the forearm.
Tactile sense sometimes lost.	Tactile sense normal.
Often neuralgic pains in joints of the affected region and in the spine.	Pain may precede the other symptoms, rarely persists.
Occasional Romberg symptom. Unsteadiness of movements. Paralysis of one vocal cord; of tongue or face. Dysphagia. Dyspnoea. Cardiac irregularity. Inequality of pupils. Occasional nystagnus and ptosis. Occasional spastic paralysis of lower limbs.	No Romberg symptom.
Bones may become thick and brittle and tabetiform joint changes may occur.	Rarely any affection of bones (excepting necrosis from felon) or joints.
Bilateral in eighty per cent.	Bilateral in forty-five per cent.
<i>Mains de prédicateur</i> in consequence of predominance of extensor paralysis [Morvan].	<i>Main en griffe</i> in consequence of predominance of flexor paralysis.
Symptoms usually develop slowly, increasing gradually in the course of years; death from exhaustion or impairment of function. Recovery rare.	Symptoms usually develop rapidly; most often confined to the forearm and hand. No extension of symptoms in from ten to forty years. Recovery, or at least marked improvement, not infrequent.
Joffroy and Achard (14) reported a necropsy made on a woman who had, forty-five years before her death, <i>painful</i> felons of both hands, leaving deformities of the fingers resembling Morvan's disease; sensibility both to pain and heat was, just before her death, greatly diminished in the	

palmar surface of her hands and fingers, and the tactile sensibility was diminished; but there was no muscular atrophy and the electrical reactions were normal. She also had kyphosis. At the necropsy not only was a cavity found in the spinal cord, but the nerves of the forearms had undergone extensive degenerations; these latter they regard as secondary to the lesion in the spinal cord, just as is the peripheral neuritis that has been observed in posterior spinal sclerosis. It might be questioned whether, excepting in physical appearance, this case presented any similarity to Morvan's disease. The felons were painful; the deformities that followed them did not interfere with the usefulness of the hands; the muscles were not atrophied; the electrical reactions were normal; and the sensory disturbances occurred at the age of seventy-five, when sensation would naturally be rather sluggish, and even then a temperature of 140° F. was recognized as something warm, and the pin prick was indistinctly felt in the thickened skin of the palm and fingers.

We do not desire to maintain that cases of myelosyringosis do not present symptoms in the earlier stages of the disease closely simulating all the phenomena of Morvan's disease; and it is furthermore probable, as Joffroy and Achard have stated, that lesions in the bulb may produce such symptoms, and that supposed cases of Morvan's disease have really been cases of myelosyringosis. But we would maintain that cases of the latter disease of sufficiently long standing will present later and more serious complications than those reported as characteristic of the former malady.

That it is not necessary to found the existence of the disease on a pathological condition in the spinal cord is, we think, demonstrated by the observations of Charcot, who has found sensory dissociation in hysteria just as it is observed in the disease under consideration, and myopathic phenomena also. These would leave the felons as the single absent symptom, and we know their presence is due to a definite cause. Minor, of Moscow, has observed sensory dissociation in traumatic myelæmatoma; and the presence of this dissociation is so frequent in anæsthetic leprosy that the possibility of the identity of that and Morvan's disease has been broached.

For instance, Dr. Zambaco (12) has held that both myelosyringosis and Morvan's disease are identical, and that the disease is only a form of anæsthetic leprosy that has been, so to speak, attenuated by the manners and climate of Europe; this has been warmly controverted by Thibierge (16), and one of us can personally state that there is no resemblance between the present case or those reported cases that have been consulted and the cases of anæsthetic leprosy he has observed in the southern American states and in Norwegian leper hospitals.

We believe that Raynaud's disease, erythromelalgia, and sclerodactylia are sufficiently typical not to be confused with Morvan's disease.

While, therefore, it is to be distinguished from myelosyringosis, hysteria, and, in leprous countries, from anæsthetic leprosy, we believe the presence of other phenomena in those cases will enable a diagnosis to be made.

From the preceding presentation of facts, and our own

experience with myelosyngosis and neuritis, we infer that the typical cases of Morvan's disease may be due to a peripheral neuritis. On the other hand, we have conceded that cases of myelosyngosis may so closely resemble Morvan's disease as to make a distinction impossible; but the strict limitation of the disease usually for many years and the early appearance of the painful felons, as well as the improvement, if not recovery, in given cases would weigh strongly in favor of the diagnosis of Morvan's disease rather than myelosyngosis. And, lastly, it must be conceded that it is possible for an ascending neuritis to lead to gliomatous degeneration in the central canal of the spinal cord, such cases presenting later the typical clinical features of myelosyngosis.

## A NEW METHOD OF TREATING ACUTE URETHRITIS.\*

BY B. E. VAUGHAN, M. D.,

ATTENDING SURGEON, NEW YORK DISPENSARY;  
ASSISTANT ATTENDING SURGEON, NEW YORK CANCER HOSPITAL, ETC.

WHEN I began the work for this paper I intended to speak of my results in treating urethritis at the New York Dispensary, where I have had during the past two years about two thousand two hundred cases. But in the past three months I have been developing what I may call a new plan of treatment, which, although not new in all its details, is enough so, I think, to warrant such a designation.

I use the term *acute* urethritis to include all forms of acute inflammations of the anterior urethra, whether specific or non-specific—first, because I did not have the time to make microscopical examinations, and, second, because the same rules of treatment apply, I think, to all *acute* cases.

I can not expect that my method of treatment will be approved by all, but I hope it may call out full discussion and expression of opinion which may tend to throw more light on the treatment of a disease which by many is considered hardly worse than a cold, but the results and complications of which cause many deaths and so much suffering.

In a conversation with Dr. Bangs a few months ago, he said, in answer to my question, How he treated acute ure-

thritis, that he had no routine treatment, but followed surgical indications, rest, drainage, and soothing applications to the mucous membranes. It impressed me as being so rational that I made it my basis for work, and have tried to follow it out in my treatment of cases.

Dr. Powers asked me to try dermatol (subgallate of bismuth), an astringent, drying, non-irritating, and non-poisonous drug, which he describes in the *Medical Record* of October 17, 1891. I first tried it in suspension, as it is insoluble, but the results were negative. Subsequently I succeeded in finding a vehicle which has proved satisfactory.

I am indebted to Daggett & Ramsdell, of 328 Fifth Avenue, for a vehicle which seems to answer every requirement, known under the name of *plasment*. They have furnished me the following notes:

"Plasment consists of the mucilaginous principle extracted from *Chondrus crispus* and *Cetraria islandica* (Irish and Iceland moss) combined with Siam benzoin and glycerin. The steam heat used in the extraction, together with other details of the process, render the preparation aseptic and it keeps perfectly. It combines readily with all substances used in dermatology, in most instances producing preparations which are superior, from a pharmaceutical point of view, to ointments. We have used it extensively in the prescriptions of several of our leading dermatologists combined with such remedies as resorcin, salicylic acid, ichthyol, sulphur, oils of cade and tar, bismuth, zinc oxide, creasote, starch, carbolic acid, potassium iodide, iodine, subiodide of bismuth, dermatol, aristol, mercury, boric acid, etc., in all cases giving great satisfaction both to the patients and physician."

Plasment is about of the consistence of vaseline. It is a demulcent and soothing to all mucous membranes. It is soluble in water, while the oils are incompatible; it coats the mucous membranes and is readily absorbed in a canal, depositing the medicament on the membrane, and at the same time protecting and keeping apart the opposing surfaces.

With this as a vehicle I use three or five per cent. of dermatol. You will readily see how this, through mixture of the dermatol with the vehicle, increases its action, if I quote from the paper of Dr. Powers.

"Experiments were made regarding its antiseptic properties, and it was found that when the dermatol was added to a fluid nutrient gelatin, decomposition or bacterial growth was hardly hindered. The same occurs with iodoform, iodol, bismuth subnitrate, and aristol. The dermatol can take effect only when it comes in direct contact with the germs and when it is evenly mixed with the nutrient medicine. This they accomplish in the following manner: Gelatin was warmed in a reagent glass until it was just fluid (28° to 30° C.), and with it large amounts of dermatol were mixed. This was then mixed with a pure culture shaken and poured on cooled trays. As it stiffened in cooling, the dermatol was held in a uniform admixture. The anthrax bacillus, *Staphylococcus pyogenes aureus*, *Bacillus prodigiosus*, bacillus of typhus and pneumonia, were used. In all of these the growth was stopped."

Now comes the question how to best apply such a mixture to the mucous membrane that is diseased.

\* Read before the Hospital Graduates' Club.

I had a special soft-rubber catheter made by Tiemann, about five inches long, with several small openings near the end on all sides.

As a syringe I use in private cases the compressible tube such as paints come in, with a special hard-rubber tip

screwed on the end, furnished me by Daggett & Ramsdell. In this way the substance is kept absolutely clean.

In my dispensary cases, where I make a great many injections, I use a hard-rubber syringe, and fill it with a spatula after unscrewing and removing the piston. It requires very little for each injection, and a small quantity goes a long way. The catheters are made in two sizes—10 and 20 F. scale. I prefer the larger size, if the urethra is large enough, as it makes the application more thorough.

The method of treatment is as follows:

The patient is first requested to urinate, not only that he may wash out the urethra, but that it may be as long as possible before it is necessary for him to pass urine again. Then the catheter is attached to a fountain syringe (any other syringe could be used), about seven feet from the floor, filled with warm water of an agreeable temperature to the hand (best, one drachm of chloride of sodium to the pint). The catheter introduced, the water goes to the bottom of the anterior urethra and then flows back around the tube and out at the meatus. The catheter should be small enough to allow the backward flow. After douching for a minute or more, the tip of the syringe is withdrawn from the catheter, and the syringe, with dermatol in plasment, is applied, and about half a drachm injected as the syringe is gradually withdrawn. In this way the whole length of the anterior urethra is coated with the medicament.

As soon as the catheter is withdrawn, a small piece of absorbent cotton is applied over the meatus, and the patient is directed to change this frequently.

Thorough antiseptics of instruments and hands in making application.

This method of application to the urethra through a catheter was suggested by Dr. Fox, about twelve years ago, at the meeting of the State Medical Society, and I have a glass tube which Dr. Fox used at that time.

Dr. Vander Poel and Dr. Halsted used iodoform, one part, and cold cream, eight parts.

Dr. Bransford Lewis recommends vaseline and lanolin (*Med. Rec.*, Aug. 17, 1889) as a vehicle; boric acid and resorcin used as active agents with a catheter four to five inches long.

Dr. Rice (*Med. Rec.*, July 20, 1889), boric acid and glycerin, three drachms to the ounce.

Bartholow mentions subnitrate of bismuth and glycerin, and Finger lanolin, as a basis for urethral applications.

You will notice that all these vehicles are *emollients*, while plasment is a *demulcent*.

Brunton's definition for emollients is substances which soften and relax. Demulcents are substances which protect and soothe the parts to which they are applied.

You will appreciate the difficulty in dispensary practice to get patients to return daily for treatment, and also the difficulty in keeping them under observation until sure that their cures have been permanent.

I will give you the histories of a few of the average cases:

*December 4th.*—Mr. W. has had gonorrhœa several times; last time, two years ago; profuse discharge, with pain on urination and balanitis for a week. Dermatol, five per cent. in plasment. Mist. pot. bicarb., t. i. d. ℞ Potassii bicarb., gr. viij; tinct. hyoseyam., ℥iv; aquæ, ʒj.

*5th.*—Pain less; discharge improved.

*8th.*—Discharge very slight; no pain.

*10th.*—Discharge very slight; no pain.

*12th.*—Discharge very slight; no pain.

*13th.*—No discharge.

The patient was under observation for two weeks; ten days under treatment; five visits. Duration of disease, seventeen days.

*December 5th.*—Mr. B., gonorrhœa several times; last time, two years ago. Profuse discharge for a week, with pain on urination. Dermatol and plasment. Bicarbonate of potassium, as in No 1.

*10th.*—Discharge improved, but pain worse.

*12th.*—Discharge improved; pain less.

*16th.*—Only very slight watery discharge; no discomfort.

*17th.*—Slight moisture.

*18th.*—No discharge.

*19th.*—No discharge.

*21st.*—No discharge.

*23d.*—The patient considered cured.

From the beginning of treatment to the stopping of discharge, thirteen days; five visits. Duration of disease, twenty days.

*November 23d.*—Mr. M., no gonorrhœa before; discharge for two days profuse, with marked swelling of mucous membrane and severe balanitis. No injection given on first day, but bicarbonate of potassium given.

*24th.*—Increased discharge and marked pain on urination. Dermatol and plasment used. Passing catheter irritated slightly.

*25th.*—Condition about the same.

*30th.*—Patient not here for five days. Discharge still profuse.

*December 1st.*—Markedly improved. Pain on urination disappeared.

*2d.*—Continued improvement; no discomfort.

*5th.*—Continued improvement.

*8th.*—Continued improvement.

*10th.*—Continued improvement.

*11th.*—Continued improvement.

*16th.*—Continued improvement. Patient came regularly; discharge growing less. On the 30th it entirely ceased and did not return. Discharge lasting in all five weeks, but course and symptoms mild after first week.

I will also give the result of its use in two private cases, where I had acute exacerbation of chronic urethritis:

1. Young man under treatment by deep injections of nitrate of silver for chronic posterior urethritis.

After free indulgence in beer and connection with a prostitute, he came to my office with a profuse discharge. Pain and swelling of the whole penis. One application relieved all the acute symptoms and the discharge entirely stopped.

2. While patient's wife was abroad he contracted gonorrhœa. The discharge had stopped after six weeks' treatment by copaiba and injections of nitrate of silver. Two weeks after this, his wife having returned, there developed an acute urethritis following first intercourse. The discharge was profuse; the whole

mucous membrane of urethra was swollen, painful, and tender to the touch. After the first injection of the dermatol and plasment all acute symptoms subsided.

The following are histories of sixty-four cases:

No.	Name.	History.	Nature.	Treatment.	Remarks.	Length of treatment.
1	Mr. C.	Gonorrhœa twice; 1 week.	Profuse discharge, with painful micturition.	Dermatol, five per cent. twice daily; dermatol and plasment.	Improved in 3 days. All treatment stopped, but in 3 days slight return due to beer; cured by one injection.	20 days.
2	Mr. Con.	None before; 3 weeks.	Profuse and purulent discharge, with balanitis.	Dermatol and plasment.	Improved after first injection; stopped in 3 days.	3 days.
3	Mr. H.	None before; 10 weeks.	Moderate discharge.	Solution of dermatol, five per cent.	Improved in 2 days.	3 days.
4	Mr. L.	None before; 1 week.	" "	" " "	Patient did not return.	
5	Mr. R.	None before; 4 days.	" "	" " "	" " "	
6	Mr. G.	None before; 6 weeks.	Profuse discharge.	" " "	Discharged stopped in 7 days.	10 days.
7	Mr. D.	None before; 1 month.	" "	" " "	Improved in 2 days.	12 days.
8	Mr. B.	None before; 5 days.	Profuse discharge; pain on urination.	Solution of dermatol, five per cent., until 12 days, and then dermatol and plasment.	3 weeks no discharge; then 2 weeks no discharge; then slight return after drinking beer.	7 weeks.
9	Mr. S.	None before; 4 days.	Profuse discharge, and pain on urination.	Solution of dermatol, five per cent.	5 days discharge less, no pain; slight showing at meatus for 8 days, and then stopped.	13 days.
10	Mr. Z.	None before; 3 weeks.	Profuse discharge; some pain.	Solution of dermatol, five per cent.; irregular.	Less pain and discharge the following day. In 10 days only slight discharge; then no treatment for a week. Came back with epididymitis.	Discharge stopped in 3 weeks.
11	Mr. C.	Treated for nearly a month with copaiba.	Copious discharge.	Solution of dermatol, five per cent., for 2 weeks, improvement; dermatol and plasment.		3 weeks.
12	Mr. S.	None before; 1 week.	Profuse, with pain on urination.	Dermatol, five per cent. for 2 weeks; dermatol and plasment.	Improvement; stopped in 10 days.	10 days.
13	Mr. Gil.	Gonorrhœa several times; not entirely free; 5 days.	Profuse and purulent.	Dermatol and pot. bicarb. for 11 days; dermatol and plasment used.	Improved first 11 days; very slight discharge continued for 2 weeks longer, then stopped.	25 days.
14	Mr. Gar.	None before; 5 days ago.	Profuse, and pain on urination.	Solution of dermatol, five per cent.; after 3 weeks, pot. bicarb.; dermatol and plasment.	Discharge stopped in 5 days; 2 weeks later, nodule near meatus, which burst into urethra.	6 weeks.
15	J. H.	None before; 10 days.	Profuse discharge, pain, and frequent micturition.	Sol. of dermatol, five per cent.; pot. bicarb.; dermatol and plasment.	Discharge stopped in 5 days; returned in a week, cured by one injection.	12 days.
16	Mr. B.	None before; 3 weeks.	Profuse and purulent discharge; pain and chordee.	Solution of dermatol, 2 weeks; pot. bicarb.; dermatol and plasment.	Discharge stopped; returned 5 days later; stopped after 4 days.	3 weeks.
17	Mr. T.	Several times; 1 week.	Watery discharge; pain on urination.	Solution of dermatol, five per cent., 1 week; dermatol and plasment; pot. bicarb.	Improvement in 2 days; patient irregular; discharge stopped, and did not return.	24 days.
18	Mr. H.	Discharge; 4 weeks.	Quite profuse.	Solution of dermatol, pot. bicarb.	Discharge stopped in 3 days.	3 days.
19	Mr. Har.	3 days.	Moderate.	" " "	.....	11 days.
20	Mr. B.	Gonorrhœa 1 yr. ago; 1 week.	Profuse, and pain on urination.	" " "	5 days, improvement; dermatol and plasment given; cured in 4 days.	9 days.
21	Mr. J.	None before; 5 days.	Purulent and frequent micturition; balanitis; phimosis.	Solution of dermatol, pot. bicarb., 1 week; dermatol and plasment.	Improved; discharge stopped in 2 days; patient did not return.	
22	Mr. M.	Gonorrhœa 5 yrs. ago; 9 days.	Profuse; no pain.	Solution of dermatol, pot. bicarb.	Discharge stopped in 7 days.	Patient did not return.
23	Mr. R.	None before; 2 days.	Chaneroid for 1 week; discharged; pain.	Solution of dermatol, pot. bicarb.; then dermatol and plasment used.	Very little improvement, 8 days; 14 days, no discharge.	14 days.
24	Mr. Coh.	Gonorrhœa 1 yr. ago; 4 days.	Profuse, with pain on urination.	Solution of dermatol, pot. bicarb., 1 week; dermatol and plasment.	Stopped in 8 days; slight return at intervals for 3 weeks; cured.	3 weeks.
25	McG.	None before; 2 days.	Thick, white, with pain on urination.	Dermatol and plasment, pot. bicarb.	No discharge after 2 weeks; irregular treatment.	2 weeks.
26	McC.	No gonorrhœa; 2 days.	Profuse, with pain on urination.	" " "	No discharge on third visit; patient irregular; did not return for 8 days. Discharge again profuse; improvement in 4 days.	15 days.

No.	Name.	History.	Nature.	Treatment.	Remarks.	Length of treatment.
27	McD.	Gonorrhœa 1 yr. ago; 2 days.	Moderate, with pain on urination.	Sol. of dermatol, 1 week; dermatol and plasment, pot. bicarb.	Treated 1 month, although most of time no discharge.	1 month.
28	Mr. V.	No gonorrhœa; 2 days.	Profuse, with pain on urination.	" " "	" " "	1 month.
29	Mr. M.	No gonorrhœa; 2 days.	Profuse, and pain on urination.	Dermatol and plasment, pot. bicarb.	Improvement in 4 days.	
30	Mr. R.	No gonorrhœa; 3 days.	Ordinary.	Solution of dermatol, five per cent.; pot. bicarb.; dermatol and plasment.	Discharge stopped after a week; returned again in 4 days. Injection given of dermatol and plasment; 2 days better, but slight moisture in the mornings for 2 weeks.	1 month (no return).
31	Mr. Hein.	Discharge; 3 weeks.	Slight, and pain on urination.	Dermatol and plasment, pot. bicarb.	Discharge stopped in 24 hours, without perceptible return.	2 days.
32	McC.	Gonorrhœa and stricture before; 3 days.	Profuse discharge, and pain on urination.	" " "	In 2 days the discharge disappeared; but with very slight returns, without any pain or irritation, for 1 mo.	5 weeks.
33	Mr. St.	2 weeks.	Profuse discharge, and pain on urination.	For 2 weeks patient was treated by AgNO <sub>3</sub> (1 to 3,000), no improvement; dermatol and plasment, pot. bicarb.	Discharge improved after three visits; did not return for 10 days, and with another trouble; no discharge since visit.	3 days.
34	Mr. D.	Gonorrhœa 2 yrs. 2 days.	Profuse discharge; balanitis.	Dermatol and plasment, irregularly; pot. bicarb.; thirteen visits in a month.	Discharge stopped in 3 weeks, but returned and continued slightly for 1 week.	5 weeks.
35	Mr. M.	No gonorrhœa; 2 days.	Profuse; balanitis; small meatus.	Dermatol and plasment, pot. bicarb.	Stopped entirely in 5 weeks; meatus was irritated by catheter.	5 weeks.
36	Mr. S.	No gonorrhœa; 3 weeks.	Profuse.	" " "	Following day very much improved; second injection given.	Patient did not return.
37	Lewis.	No gonorrhœa; 3 weeks.	Considerable discharge, with pain.	" " "	No discharge on second and third visits; then very slight for 10 days.	12 days.
38	Mr. B.	Gonorrhœa 3 yrs. ago; 3 days.	Profuse, with pain.	" " "	No discharge at 3 weeks; patient returned 2 weeks later with discharge following use of beer.	5 weeks.
39	Mr. G.	Gonorrhœa 2 years; 1 day.	Quite profuse.	" " "	Patient very irregular; cured after 5 weeks, only 6 visits.	3 weeks (not satisfactory).
40	Mr. W.	Gonorrhœa several times; 1 wk.	Discharge; pain and balanitis.	" " "	No discharge in 11 days.	11 days.
41	McG.	Several times; 2 weeks.	Ordinary.	" " "	Discharge stopped in 1 week; returned twice later due to excessive indulgence.	1 week; under observation for 4 weeks.
42	Mr. B.	Several times; 1 week.	"	" " "	Discharge stopped temporarily in 13 days; in 16 days stopped and did not return.	16 days.
43	Gross.	2 months.	"	" " "	4 days, stopped; but returned in 1 week slightly after beer in excess; stopped by one injection.	12 days.
44	Mr. J.	1 week.	Small meatus; profuse discharge.	" " "	No discharge in 19 days.	19 days.
45	Mr. G.	No gonorrhœa; 1 week.	Profuse discharge; swelling of glands and œdema of prepuce.	" " "	Stopped in 12 days; slight return at intervals for 2 weeks longer.	1 month.
46	Mr. F.	No gonorrhœa; 1 week.	Profuse discharge; chancere and balanitis.	" " "	Discharge stopped in 6 days.	6 days.

8 did not return.  
3 under treatment.

In all these cases there has developed only one case of epididymitis, and in that the patient had absented himself a week from treatment.

Other complications—such as cystitis and balanitis—have been absent, unless present at beginning of treatment.

*Conclusions.*—1. That in the treatment of acute urethritis soothing applications rather than irritants should be used.

2. That the passage of the soft-rubber catheter recommended does not, as a rule, irritate the urethra; that if it does it should not be used.

3. That plasment is an excellent vehicle for urethral medicaments.

4. That dermatol in plasment is the most efficacious drug I have used in urethritis, although I have used no other drug with plasment.

5. That treatment by the above-described method has produced a milder course and fewer complications than that with other remedies that I have used.

*Note.*—Since the foregoing was written, six of the patients reported as cured have returned with a discharge. In all these cases there was a history of previous attacks, and examination showed evidences of chronic urethritis.

Although the results of treatment do not make a brilliant showing in these tables, yet I think you will all admit that it is far above the average results.

I do not allege that urethritis is aborted by this treatment, but that, when regularly applied, it allays the inflammatory symptoms and makes the patient much more comfortable, shortening the course and preventing complications.

### ANALYSES OF TWO HUNDRED CASES OF ERRORS OF REFRACTION.\*

By H. BERT ELLIS, B. A., M. D.,

LOS ANGELES, CAL.,  
PROFESSOR OF PHYSIOLOGY IN  
THE COLLEGE OF MEDICINE OF THE UNIVERSITY OF SOUTHERN CALIFORNIA.

THESE analyses are based upon cases met in private practice during the past two years, and I offer them to your consideration, with a few remarks in the shape of explanations and conclusions, not in the hope that there is anything new in them which you are not already all well aware of, but with the idea that by the constant repetition of well-known facts the foundation may be laid for the more

\* Read before the Southern California Medical Society at its eighth semi-annual meeting, held at Riverside, December 2 and 3, 1891.

general attention of the profession to eye-strain as a causative factor in human ailments.

I may state, as a prefatory note, that in the preparation of these tables I have followed closely in the path blazed by Dr. George M. Gould, of Philadelphia, in a paper read in the Section on Ophthalmology, at the forty-second annual meeting of the American Medical Association. I have trod in Dr. Gould's footsteps because my experience, although much more limited, has been quite similar; and further because, if my summaries are worth anything, they will be the more valuable modeled after a standard.

During the time covered by the cases here recorded in my ophthalmic practice I have had but eleven patients whose conditions I did not consider would be benefited by the wearing of glasses. Of these eleven, three I have noted as emmetropic; but it is only of one of them that I can speak with assurance. Eight had very slight hyperopic or myopic errors, but were without ocular or other reflex neuroses. That is to say, 94.5 per cent. of my eye cases have needed glasses, and only one half of one per cent. have been certainly emmetropic. Of the two hundred cases recorded, forty-three were presbyopic; that is, 21.5 per cent.; and of the remaining one hundred and fifty-seven, one hundred and one were examined under a mydriatic; the others should have been, but in private practice it is many times almost impossible for the business men or the women who depend upon their eyes for their daily bread to stop their work for even two to four days, the time necessary when homatropine is employed.

The proportion between males and females is favorable to the latter, the figures showing one hundred and fifty girls or women and only fifty boys and men. This disproportion may be accounted for by the difference in habits and out-of-door exercise, these rendering the women less physically perfect, giving them less resistance, and making them—with their highly wrought nervous systems—greater slaves to surrounding conditions.

TABLE I.

General Refraction of Three Hundred and Ninety-five Eyes.

	Eyes.	Per cent. of H.	Per cent. of all.
Simple hyperopia.....	116	36.2	29.3
Simple hyperopic astigmatism.....	61	19.1	15.5
Hyperopia with astigmatism.....	143	44.7	36.2
Total hyperopic.....	320	100	81
		Per cent. of M.	
Simple myopia.....	19	25.3	4.8
Simple myopic astigmatism.....	18	24	4.6
Myopia with astigmatism.....	38	50.7	9.6
Total myopic.....	75	100	19
Grand total.....	395	....	100

In Table I, I have given the general refraction, and in it you will perceive that eighty-one per cent. have been hyperopic; and of these about sixty-three per cent. were astigmatic. Among the myopes, seventy-five per cent. had more or less astigmatism. That Dr. Gould found eighty-three and ninety-one per cent., respectively, of hyperopic

and myopic astigmatism, where I found but sixty-three and seventy-five per cent., may be explained by the fact that all of his cases, excepting those far advanced in presbyopia, were examined under a mydriatic; while twenty-eight per cent. of my patients would not be subjected to such inconvenience.

The percentages in the subdivisions of the myopic and hyperopic table you will find very much closer than Dr. Gould's analysis shows. Thus simple H. and simple M. were thirty-six and twenty-five per cent. Ah. and Am. were nineteen and twenty-four, while the compound Ah. and compound Am. were 44.7 and 50.7 per cent., respectively.

6.50.....	2	..	2			
.....	116	143	259	259	100	65.5

Table II is a summary of the refraction of the hyperopic cases excluding the astigmatic errors. One third of the hyperopes and about a quarter of all the cases had an error of 0.50 D. or less. Sixty-four per cent. of the hyperopes and forty-two per cent. of all the patients had an error of 1 D. or less, and I corrected a great majority of these low errors. Only three per cent. of the hyperopic cases had errors over 5 D.

An examination of Table III—a summary of myopia without the astigmatism—reveals quite a different percentage relation. Only thirty per cent. of the myopes had an error of 0.50 D. or less; and only forty-two per cent., a little over a third, had 1 D. or less; while nineteen per cent. had between 5 D. and 17 D.

Among the hyperopes, sixteen per cent. had errors over 2 D., while forty-four per cent. of the myopes had corresponding errors, showing that errors of a high degree occurred three times more frequently among the myopes.

The hyperopic and myopic astigmatic errors are summarized in Table IV, and include both the simple and compound corrections. The same facts are to be noted in this table which I have already called your attention to in the two preceding tables—namely, the low degrees, 1 D. or

In astigmatism the question of axes is one of considerable interest to the oculist therefore I have carefully tabulated two hundred and sixty eyes in Tables V and VI. In the hyperopic astigmatic eyes I found fifty per cent. according to rule—that is, with axes at 90°. Among the unsymmetrical are classed fifteen cases, in which one axis was 90°. This would make fifty-seven per cent. of astigmatic hyperopic eyes, according to rule. Sixteen per cent. had their axes at 180°, thirty-one per cent. were unsymmetrical.

Sundry not in the above.....	3	33.3	6.8
Total.....	9	100	20.5
Grand total.....	44	....	100

Among those with myopic astigmatism I found thirty-six per cent. according to rule—that is, with axes at 180°; to these we may add those unsymmetrical cases in which the astigmatic angle of one eye was 180°, which makes forty-three per cent. of my astigmatic myopic eyes which had their axes according to rule. Twenty-one per cent. of the myopic astigmatic eyes had axes at 90°, while twenty-seven per cent. were unsymmetrical.

Of all astigmatic eyes, fifty-one per cent. had their axes at 90°, and seventy-four per cent. had their axes at either 90° or 180°. From this you see that, in any given case, we are more than twice as likely to find the angle of astigmatism at 90° than at 180°, and three times as likely to find the angle at 90° or 180° as at all other angles.

Besides those with axes at 90° or 180°, I had but six symmetrical axes, or four per cent.

About thirty per cent. of both my astigmatic hyperopes and myopes had unsymmetrical axes; the total number of cases was forty-four. Fifty-nine per cent. of these had one of their axes at 90° or 180°, but the axes of the other eyes were exceedingly variable, following no rule. In four the axes were  $\frac{90^\circ}{75^\circ}$ ; in three cases  $\frac{90^\circ}{60^\circ}$ ; in two cases  $\frac{90^\circ}{70^\circ}$ ; in

two other cases  $\frac{90^\circ}{105^\circ}$ ; and in two patients  $\frac{180^\circ}{45^\circ}$ ; no other two cases were alike.

Of the other eighteen asymmetrical cases, there was but one in which the axes of both eyes were the same; and there were no two cases with the same astigmatic angles.

In the application of glasses to several of my astigmatic patients I have had no little trouble, because of the absolute non-acceptance of a glass at a certain angle on the return of accommodation which had been unmistakably indicated under a mydriatic. At first I was greatly puzzled, and I still am, by these cases; for as yet I am certainly "at sea," in so far as a *satisfactory* explanation is concerned. "Spasm of the accommodation" is but a cloak to hide our ignorance. The explanation which to me seems to be the most reasonable is "irregular astigmatism"—that is, the curvature near the periphery of the cornea differs from that of its center, through which the individual usually looks.

Without entering further into the details of these tables, which I can not expect you as a body to be deeply interested in, let me call your attention for a few minutes to the manifestations of eye-strain which, as general practitioners, we are constantly brought in contact with.

The eye-strain reflexes which I have been able to trace with reasonable certainty in my practice I have classified in Tables VII and VIII.

TABLE VII.

*Eye-strain with Ocular Reflexes.*

SYMPTOMS.	Cases.	Per cent. of all refraction.
Pain in eyeballs.....	13	6.5
Partial ptosis.....	4	2
Blepharospasm.....	5	2.5
Blepharitis, sties, etc.....	5	2.5
Conjunctivitis excluded except in.....	8	4
Lacrymation.....	7	3.5
Photophobia and distress from light } Direct....	20	10
Photophobia and distress from light } Reflected....	18	9
Total.....	80	40

TABLE VIII.

*Reflex Neuroses of possible Ocular Origin.*

SYMPTOMS.	Cases.	Per cent. of all reflex neuroses.	Per cent. of all refractive cases.
Headaches.....	93	87.7	46.5
Digestive and assimilative disorders...	6	5.7	3
Mental symptoms, loss of memory, etc.	2	1.9	1
Blind spells.....	4	3.8	2
Insomnia.....	1	0.9	0.5
Total.....	106	100	53

Table VII contains all those cases in which the eye-strain has manifested itself by *ocular* reflexes. Forty per cent. of all my patients with refraction have had some ocular manifestation. Many others had conjunctivitis, blepharitis, or some other symptom; but whenever these cases were specific, or could be traced to some definite cause, they have been excluded from this summary.

The most common ocular reflex was some degree of

photophobia or distress from light. In southern California, where we have such perpetual sunshine, this is a symptom of no little moment. In the table I have grouped these cases under two heads for convenience, because of my belief of the different causes producing the symptoms, and the different methods employed in relieving the same.

These subdivisions are photophobia from the *direct rays* which, outside of the ocular defect, are irritating from intensity; and photophobia from *reflected rays*, from our artificial stone sidewalks, asphalt streets, and nearly white country roads. The irritation in these cases I believe to be chiefly due to the red or heat rays. If correction of the defects fails to relieve these symptoms, I prescribe for those who suffer most from the direct rays varying shades of "London smoke" glasses; but for those whose great distress arises from the reflected rays I order blue.

Pain in the eyeballs was another common symptom, as was also lacrymation. Although forty per cent. of all the patients had some ocular symptom, in the great majority of these cases the ocular reflex was slight and not to be compared with other reflex neuroses. Some patients had many ocular and reflex neuroses, so that there was considerable duplication and no little indefiniteness as to origin, although in the majority of cases I was inclined to the belief that they should be ascribed to eye-strain.

The reflex neuroses I have placed in Table VIII; of these, headaches formed eighty-eight per cent. and 46.5 per cent. of all refractive cases. The character of the headaches has been variable, and justifies an additional descriptive summary, which is to be found in Table IX.

TABLE IX.

*Headaches.*

VARIETY.	Cases.	Per cent. of all headaches.	Per cent. of all refraction.
Frontal, brows, temples.....	27	29	13.5
Sick headaches.....	11	11.8	5.5
Neuralgic headaches.....	12	13	6
First frontal, then extending to vertex.	2	2.1	1
First frontal, then extending to occiput.	3	3.2	1.5
First frontal, then general.....	2	2.1	1
Vertex.....	6	6.5	3
Occiput.....	7	7.6	3.5
General.....	20	21.5	10
Dizziness.....	3	3.2	1.5
Total.....	93	100	46.5

Twenty-nine per cent. had frontal, brow, or temporal headaches; twenty-one per cent. had general headaches; thirteen per cent. were of a neuralgic character; while twelve per cent. had sick headaches.

In many the headaches would at first be frontal, but before they ceased would become vertical, occipital, or general. If we leave off the forty-three patients who were presbyopic, then in sixty per cent. of the patients headache was a marked symptom, and in probably fifteen per cent. more it was an occasional, but not a prominent, symptom.

The importance of headaches can hardly be overestimated. It is certainly a conservative estimate which places sixty per cent. of all headaches as due to ocular defects and continued headache works ruin slowly, but none the

less certainly. Some maintain that at least seventy-five per cent., and others that ninety per cent., of all headaches are caused by some error of the seeing apparatus; and at least two thirds of the patients who have their refraction corrected before twenty-five to thirty years of age are cured or greatly alleviated; but those who are older may be benefited, or even completely relieved; but, as a rule, the length of time for the accomplishment of this result is considerable.

I have said nothing about several of the reflex neuroses, and I have given no summary of muscular insufficiency, because I desired to keep this paper within reasonable limits as to length, and make it of general as well as special interest.

107 N. SPRING STREET.

**Tannin in Tea.**—"Some examples which have been forwarded to us," says the *British Medical Journal*, "of the results of analyses for tannin and theine in tea indicate considerable variation in the amount of tannin, according to the quality of the tea and the state of growth at which it is picked. In some blends of China teas the percentage of tannin extracted by infusion for thirty minutes was 7.44; theine, 3.11; and a similar result was given in the examination of the finest Moning; while, on the other hand, with fine Assam tea a percentage of 17.73 of tannin by weight was extracted after infusion for fifteen minutes, and two blends of Assam and Ceylon tea gave, respectively, 8.91 and 10.26 of tannin. On the whole, it is probable that the Indian teas are much more heavily loaded with tannin than the China or Japan teas. Moreover, the common method of prolonged infusion in boiling water is well calculated to extract all the tannin, while it dissipates the flavor of the tea. To be drunk reasonably, tea should not be infused for more than a minute, and with water of which the temperature does not exceed 170° F. It should be taken without sugar or milk, which would drown the flavor of the delicate and aromatic infusion thus obtained. This at least is how tea is drunk both in China and Japan, whence we have borrowed the use of it. With our European method of prolonged infusion in boiling water we destroy all the best flavor of the tea, and we extract such heavy proportions of tannin as to cultivate indigestion as the result of tea-drinking. Indigestion is unknown among tea-drinkers in the East, and it is in all probability only the result of our defective use of the leaf."

**Filariasis.**—"Among twenty-six officers and colonial officers admitted to the Val-de-Grâce Hospital between May 1, 1890, and February 1, 1891," says the *Lancet*, "Professor Moty observed four cases of the above disease, and two other cases in the parents or friends of the patients. Four, however, of those admitted to the hospital had been abroad for so short a time that they may be left out of the calculation, leaving six cases among twenty-two persons who had spent a considerable time in the colonies. In spite of its frequency, this disease does not appear to be generally recognized abroad, as in none of the above cases had it been diagnosticated. It was only upon undertaking an operation for the radical cure of a supposed hernia that the tumor was found to consist of dilated lymphatics. Professor Moty came to the following conclusions: That filariasis is an aseptic parasitic disease due to the presence of the *filaria sanguinis hominis*; that it is of frequent occurrence in the French colonies, and has been recently met with in New Caledonia. It most often appears as an enlargement of the glands and lymphatics of the groin and spermatic cord, due to the irritation of the *filaria* and its embryos. It can be recognized by such symptoms as ehyuria, hamaturia, etc.; but the diagnosis in each case should be confirmed by the detection of the embryos in the blood. Neither internal nor palliative treatment is of the slightest use. Excision or amputation is necessary in severe cases, and is attended with the happiest results, the removal of the hypertrophied tissue causing the adult *filaria* to disappear."

NEW YORK, SATURDAY, APRIL 30, 1892

PHYSICIANS' BUSINESS METHODS.

In a recent address to medical graduates the Rev. Dr. Alexander very pertinently remarked that the physician's first duty to society was to make a living and keep out of the poor-house. That this will be a question of most vital interest in the near future with a majority of the young men to whom the remark was addressed no medical man of ten years' experience will doubt. It is true that the primary object of medicine as a profession is not the accumulation of wealth. A physician who has amassed a fortune by the practice of his profession is an extreme rarity. Many acquire a competence, and it is the duty of every man, professional or non-professional, to do so if it is within his power. The philanthropic idea is stronger in medicine than in any other calling, except perhaps that of the clergyman. But the doctor must pay his taxes or rent; he must eat, drink, and be clothed; he must be supplied with instruments and books; he must support his family and educate his children. The effusive thanks of grateful patients do not, unfortunately, pay the bills. Fees alone will do that.

We thoroughly believe that medicine is a calling, not a trade; that the tradesman and business man may with entire propriety adopt methods that would degrade the physician. He can not practice his profession on strict commercial principles without losing his self-respect and forfeiting the esteem of the community. There is, however, a business side to medical practice which the doctor is proverbially lax in managing. The amount of work he does is by no means the key to the amount of his income. Laxity in business matters will explain the apparent lack of success of many a physician. Some men are wholly lacking in practical business capacity; others, from indolence or overwork, neglect to give proper attention to their collecting; while others, from failure to appreciate the value of their own services, obtain less remuneration than is their due. People are very apt to estimate a man according to the estimate he places upon himself. If his price is habitually below the customary fees of the locality in which he lives, and he is diffident in enforcing his claims, he need not be surprised if his patients put a low estimate upon his worth and are slow in paying his bills. Just regard for the poor and the unfortunate is a duty which very few physicians are inclined to evade. The laborer is worthy of his hire, and there is no more worthy laborer than the conscientious physician. He is under no moral obligation whatever to deprive himself and his family of remuneration justly due him from the well-to-do. By cutting rates he gains nothing in the long run. He injures not only himself but his fellow-practitioners by degrading the value of medical service.

There is perhaps no more fruitful source of loss to the physician than laxity in rendering bills. There is great truth in the old saying that short accounts make long friends. It is frequently said that doctors' bills are hard to collect. If this is true, the doctor is in many instances to blame—not because of lack of professional skill, but because the bill is so long delayed that the patient has forgotten the matter and his gratitude has evaporated. The age of long credits in commercial life is gone. This is largely true also of professional work in the great centers of population. In some country localities and among certain city physicians it is not true. They allow accounts to run for months or years without rendering a bill. The doctor's bill thus becomes a formidable thing and is hard to pay, and must usually be discounted. If rendered at short intervals, before it has attained to great size, it is grouped with the current expenses and is quickly paid with comparatively little effort. The doctor's care, and labor, and sleepless nights are then all remembered, and the patient feels that he is paying money for value received, and does not ask for a discount. Frequent bills, while they need not show a mercenary or grasping spirit, do show that the doctor lives by his practice and expects remuneration for his labor. It is not wise to place anything on a bill that will seem to be an apology for rendering it, such as the statement "bills rendered quarterly." A bill should be rendered as a matter of course at stated intervals, which will vary somewhat in different communities.

The struggle to make a living is for most medical men a hard one. They enter on their career without having had the slightest instruction in professional ethics or business methods, and the mistakes of the first years are by no means confined to diagnosis and treatment. Success as a practitioner depends almost, perhaps quite, as much upon social and business capacity as upon professional training. There is no person deserving of more pity than the scholarly and brilliant physician hampered by his inability to read and deal with human nature, and cramped through life by bad business methods and lack of financial ability.

### MINOR PARAGRAPHS.

#### THE ALUMNI ASSOCIATION OF CHARITY HOSPITAL.

THE well-attended and enjoyable annual dinner of this association, on Saturday evening, the 23d inst., calls to mind anew the good influence that such organizations are exerting. There is no danger that the brotherly feeling they promote will degenerate into cliquism, for each of them generously invites representatives of the others to take part in its festivities and in much of its other proceedings. It is a good thing for any hospital to have the ex-officers of its house staff thus banded together.

#### RETROSTERNAL AUSCULTATION.

IN the March number of the *Revue de médecine* Dr. Boy-Teissier, of Marseilles, presents the advantages of what he calls retrosternal auscultation in many cases of cardiac, and especially of aortic disease. With the patient lying on his back, the head being but slightly raised, a stethoscope having an aperture only

12 millimetres in diameter is applied just above the interclavicular notch and pressed moderately backward and downward, so as to bring the tube into approximate parallelism with the long axis of the body. It is said that one readily learns the art of doing this without discomfort to the patient in cases where the anatomical conditions are favorable, and that no artificial bruits are produced by the pressure of the instrument. The sounds heard in this method of auscultation are all such as can be elicited also by presternal auscultation, but they are heard with much greater distinctness.

#### A MEDICAL DRAMATIST.

AT one of the New York theatres, on Wednesday of this week, a matinée performance was given of a play entitled *An American M. D.*, written by Dr. J. Mount Bleyer, a New York physician of literary proclivities. We have often spoken encouragingly of medical men's ventures in verse, fiction, and other branches of general literature, and we think it speaks well for our profession that such attempts are growing commoner.

#### AN ADDITION TO OUR NOMENCLATURE.

THE *New York Times* has an excellent department of Answers to Correspondents, but one day last week it excited our regret by adding to the already endless catalogue of names of diseases that of "locomotor agitans," which it makes a synonym of locomotor ataxia.

#### ITEMS, ETC.

**The Keeley "Cure" for Inebriety.**—At the annual meeting of the Hampden District Medical Society, of Massachusetts, held on the 20th inst., the following preambles and resolution were adopted:

*Whereas*, According to common and newspaper report and upon information and belief, it is known that a member of this society and fellow of the Massachusetts Medical Society in regular standing has, by associating himself with one of the most notorious impostors of this century, in the application and use of a remedy for the cure of inebriety, called "bichloride of gold," and whose exact composition it is pretended is known only by, and is the sole property of, a certain individual; and

*Whereas*, No such stable chemical combination is possible, and the substance actually used with so much secrecy and profit to the proprietor is and has been employed in suitable cases for years by regular physicians, who well know its limitious and dangers; and

*Whereas*, By associating himself with a regular physician this pretender hopes to gain prestige and the quasi-indorsement of the regular profession, thus enabling him longer to delude the public; and

*Whereas*, The association of a regular physician in such a capacity is calculated to injure the public and is degrading to those who are in fellowship with such physician, and recognizing that "naught but evil can finally result from trifling with moral or physical facts, and that it is better to cure rightly and really than wrongly and delusively," and that by the "humbuggery of secrecy, delusion, and hypnotic suggestion," a far less number will, in the end, receive benefit; and

*Whereas*, It is the opinion of the members of this society that the use of the drugs, in the manner employed, for the cure of inebriety by the aforesaid impostor, produces a cerebral stimulation with intellectual disorders which are sometimes quite serious, together with other grave nervous troubles, themselves constituting a form of inebriety frequently leading to insanity and suicide, and a lowering of vitality, rendering the patient less able to resist and recover from ordinary diseases; and

*Whereas*, In those cases of inebriety claimed to have been cured by means of this pretended secret method of treatment, it is our opinion that such cures resulted not because of said treatment, but in spite of it, and there seems little doubt that hypnotic suggestion played an important part in effecting said cures, and it is our opinion that in all

of the so-called "cures" the result attained could have been better secured by improving the moral condition of the patient, by the use of tonics or hydrotherapeutics, regulating nervous action, and by attention to the digestive tract, without subjecting the patient to the dangers of another form of inebriety, and without the element of secrecy. It is, therefore,

*Resolved*, That this society hereby directs its president to refer this subject to a proper committee, who shall, before the next regular meeting, ascertain if any member of this society has identified himself with the manufacture, sale, distribution, or use of any secret remedy, contrary to the code of ethics under which this society is organized, and, if so, that such member or members be recommended for expulsion from membership in this society at said next regular meeting.

**Changes of Address.**—Dr. Henry T. Byford, to Nos. 34 and 36 Washington Street, Chicago (May 1st); Dr. C. E. Lockwood, to No. 59 West Thirty-fifth Street (May 1st); Dr. William Oliver Moore, to No. 85 Madison Avenue; Dr. J. Rendell, to No. 635 Bedford Avenue, Brooklyn (May 1st).

**The Middleton Goldsmith Lecture**, to be given before the New York Pathological Society by Dr. Francis P. Kinnicut, at the Academy of Medicine, on Wednesday evening, May 11th, at 8.30 o'clock, will be on the subject of New Outlooks in the Prophylaxis and Treatment of Tuberculosis.

**Marine-Hospital Service.**—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the three weeks ending April 16, 1892:*

- BAILLIACHE, P. H., Surgeon. Granted leave of absence for seven days. March 29, 1892.
- PURVIANCE, GEORGE, Surgeon. Detailed as chairman of Board for Physical Examination of Officer, Revenue-Marine Service. March 30, 1892.
- HAMILTON, J. B., Surgeon. Detailed as chairman of Board for Physical Examination of Surfmen, Life-Saving Service. March 31, 1892.
- GODFREY, JOHN, Surgeon. Detailed as inspector of immigrants, Port of New York. April 14, 1892.
- MEAD, F. W., Surgeon. Detailed as chairman of Board for Physical Examination of Officers of Revenue-Marine Service. April 16, 1892.
- BANKS, C. E., Passed Assistant Surgeon. Ordered to examination for promotion. April 14, 1892.
- CARNICHAEL, D. A., Passed Assistant Surgeon. When relieved at Port Townsend, Washington, to proceed to San Francisco Quarantine for duty. April 8, 1892.
- MCINTOSH, W. P., Passed Assistant Surgeon. When relieved at San Francisco Quarantine, to proceed to New Orleans, La., for duty. April 8, 1892.
- PETTUS, W. J., Passed Assistant Surgeon. Granted leave of absence for thirty days. April 12, 1892.
- MAGRUDER, G. M., Passed Assistant Surgeon. When relieved at Portland, Oregon, to proceed to Port Townsend, Washington, for duty. April 8, 1892.
- KINYOUN, J. J., Passed Assistant Surgeon. Detailed as chairman of Board for Physical Examinations of Candidates and Officers, Revenue-Marine Service. March 30, 1892. Detailed as recorder of Board for Physical Examination of Officers, Revenue-Marine Service. April 16, 1892.
- VAUGHAN, G. T., Passed Assistant Surgeon. Detailed as recorder of Board for Physical Examination of Candidates and Officers, Revenue-Marine Service. March 30, 1892.
- GEDDINGS, H. D., Assistant Surgeon. Ordered to examination for promotion. March 29, 1892.
- WEITENBAKER, C. P., Assistant Surgeon. Detailed as recorder of Board for Physical Examination of Surfmen, Life-Saving Service. March 31, 1892. Ordered to examination for promotion. April 5, 1892.
- PERRY, J. C., Assistant Surgeon. To proceed to Gulf Quarantine for temporary duty. April 9, 1892.
- YOUNG, G. B., Assistant Surgeon. When relieved at St. Louis, Mo., to proceed to Portland, Oregon, for duty. April 8, 1892.
- STIMPSON, W. G., Assistant Surgeon. Detailed as recorder of Board for

Physical Examination of Officer, Revenue Marine Service. March 30, 1892.

BROWN, B. W., Assistant Surgeon. Detailed as chairman of Board for Physical Examination of Officer, Revenue Marine Service. April 1, 1892. To proceed to Port Townsend, Washington, for temporary duty. April 8, 1892.

ROSENAU, M. J., Assistant Surgeon. When relieved at New Orleans, La., to proceed to St. Louis, Mo., for duty. April 8, 1892.

COPER, L. E., Assistant Surgeon. To proceed to Buffalo, N. Y., for temporary duty. April 8, 1892.

EAGER, J. M., Assistant Surgeon. To proceed to Gallipolis, Ohio, for temporary duty. April 8, 1892.

GARDNER, C. H., Assistant Surgeon. To proceed to San Francisco, Cal., for temporary duty. April 8, 1892.

#### Society Meetings for the Coming Week:

MONDAY, *May 2d*: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society, New York (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Corning, N. Y., Academy of Medicine; Boston Medical Association (annual); Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, *May 3d*: New York Obstetrical Society (private); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg, N. Y., Medical Association; Hudson, N. J. (Jersey City—annual), and Mercer, N. J. (annual), County Medical Societies; Connecticut River Valley Medical Association (Bellows Falls, Vt.); Androscoggin, Me., County Medical Association (Lewiston); Baltimore Academy of Medicine.

WEDNESDAY, *May 4th*: Society of the Alumni of Bellevue Hospital; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond, N. Y. (Stapleton); Bridgeport, Conn., Medical Association; Penobscot, Me., County Medical Society (Bangor); Essex North (annual—Haverhill) and Plymouth (annual), Mass., District Medical Societies.

THURSDAY, *May 5th*: New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, N. Y.; Medical Society of the County of Orleans (semi-annual—Albion), N. Y.; United States Naval Medical Society (Washington); Boston Medico-psychological Association; Obstetrical Society of Philadelphia; Ocean, N. J., County Medical Society (Tom's River).

FRIDAY, *May 6th*: Practitioners' Society of New York (private); Baltimore Clinical Society.

SATURDAY, *May 7th*: Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

#### Answers to Correspondents:

*No. 381.*—For bacteriological investigations and for examinations of blood, a Zeiss's twelfth immersion; for the other work mentioned, the same maker's objectives A and E. In each case, of course, a suitable eye-piece should be used.

### Letters to the Editor.

#### NOTE ON THE DISAPPEARANCE OF SUGAR IN THE URINE OF DIABETICS JUST BEFORE DEATH.

103 EAST SIXTEENTH STREET.

To the Editor of the *New York Medical Journal*:

SIR: Having recently occasion to review the works of Ebdstein and Cantani, I noticed that in neither was any explanation offered of this well-known clinical fact. While I was an interne

in the London Hospital Dr. Stephen Mackenzie was making special observations upon diabetes in the wards of Dr. J. Hnghlings Jackson, having twelve cases under treatment. In some part of the study of the case a "fasting trial" was imposed of twenty-four hours to note the effect upon the production and increase and decrease of the sugar. At 10 p. m. the last meal was given. With the exception of plain boiled water, nothing whatsoever was allowed for twenty-four hours. These "fastings" having been conducted in over a hundred cases, the results were always uniform. The urine during the trial was tested every hour, the patient being called upon to pass his urine "on time." Singular to say, in all my experience I never failed to obtain "some" when the time came around. For the first few testings the percentage of sugar appears as usual, after six hours for two, three, even four trials it is augmented, then begins to decrease. With the decrease there is a fall in the specific gravity; and when this fall occurs it is always followed by the appearance of albumin at the next trial, and from this on the albumin remains. At some point after the tenth hour of fasting the sugar disappears, and very often with the disappearance of the sugar blood appears, and often I have been obliged to break the trial on this account. These trials have been so frequent that some positive relation exists between the disappearance of the sugar and the want of food. As most diabetics die a lingering death, from coma, acetonæmia, etc., they seldom receive any food or nourishment for hours before death.

Recalling the result of my observations, it would seem (aside from other theories) that the result at the end of several hours' fasting was akin to the state of the dying diabetic, and if in the living sugar can be made to disappear, why not in the dying? If this fact has been noticed before, pardon me; but I have never come across it, and it just recurred to me while reading Cantani's masterly paper.

ROBERT SAFFORD NEWTON, M. D. (N. Y.)

## Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN ORTHOPÆDIO SURGERY.

*Meeting of March 18, 1892.*

Dr. HENRY LING TAYLOR in the Chair.

**Asymmetry of the Extremities.**—Dr. L. W. HUBBARD presented two sisters exhibiting this condition. One child had an inch and a half shortening of the left lower extremity, and about two inches and a half shortening in the left upper extremity, which was about evenly divided by the arm, forearm, and hand. There was also a slight shortening of the left ramus of the jaw. Her younger sister also exhibited about the same amount of shortening of the left upper and lower extremities. The muscles were well developed in both. Their parents were healthy Germans, and there was no history of a similar deformity in other members of the family. An attempt had been made to explain this asymmetry on the theory that there was an unequal development of the cerebrum on the two sides.

Dr. A. B. JUDSON had seen a counterpart of these cases in a girl of eleven years, in whom the right ear and eye, as well as the right upper and lower limbs, were congenitally smaller than the left. He suggested wearing an ischiadic crutch on the larger side and a high sole on the smaller side during the period of rapid growth. He thought that hip cases treated in this way owed the disparity in length of the limbs, which was found in

the tibia as well as in the femur, partly to the disease of one and the overuse of the other. Advantage should be taken of this fact in the treatment of these cases of congenital asymmetry.

Dr. R. H. SAYRE said that many writers had denied that want of symmetry in the lower extremities was a cause of true lateral curvature, and had said that the occasional association of the two conditions was a mere coincidence. Personally, however, he believed that, if the children just presented were allowed to go on to puberty without the employment of measures to equalize the limbs, they would certainly develop true lateral curvature. In one of the cases the lack of development did not seem to him to be entirely confined to one half of the body, as the left side of the face appeared larger than the right, although the extremities were smaller on the left side than on the right. On this account he did not think the theory that this asymmetry was due to unequal development of the two halves of the cerebrum could be correct. He agreed with the previous speaker that much of the atrophy following hip disease was due to lack of use, and he therefore heartily indorsed his suggestions as to treatment.

Dr. A. M. PHELPS said that his experience had led him to believe that the shortening of the limb in hip disease was never due to anything but bone destruction, and that the employment of the treatment suggested would effect no change in the length of the limbs, although it might increase their circumference.

Dr. SAYRE said that after patients with club-foot had improved sufficiently to enable them to use their feet, it was noticed that there was not only an increase in the bulk of the feet, but also in the length of the bones. It had also been observed in colleges, where careful records were kept of the physical condition of the students, that those who exercised regularly in the gymnasium not only had larger muscles, but were taller than those who did not avail themselves of this opportunity for physical training.

**Results in Cases of Hip Disease treated by the Portable Traction Splint without Complete Immobilization except during the Inflammatory Stage; with Illustrative Cases and Photographs of Cases.**—Dr. LEWIS A. SAYRE read a paper bearing this title. (See page 477.)

Dr. JUDSON agreed with the writer of the paper that traction did not secure complete immobilization, but rather fixation or a fractional and sufficient degree of immobilization. Fixation thus produced relieved pain and hastened recovery, but did not prevent the correction of deformity, which was brought about conveniently and surely as soon as the patient, wearing the hip splint or the ischiadic crutch, was taught to observe habitually the natural rhythm of walking. Adduction and flexion were thus reduced because the limb reached outward and downward, and abduction and extension, in order to do their share of the work of progression, were equalized. He had been pleased to find that not only was deformity reduced, but also the range of motion increased in the joint when the limb was summoned in this way to do as far as it could its half of the work of locomotion.

Dr. PHELPS said that while listening to the paper he had been impressed with the striking difference between the statistics presented by the author and those published a few years ago by Shaffer and Lovett, notwithstanding all these gentlemen used the same plan of treatment. In thirty-nine cases reported by the two last-named gentlemen, nineteen patients had ankylosis and seven were in a condition almost equivalent to ankylosis. The author of the paper which had just been presented deserved to be congratulated on the large number of magnificent cures that he had obtained. The speaker admitted that he had become somewhat prejudiced against the long traction splint, partly as

a result of experience and partly because of the publication of the statistics which he had just quoted. Where ankylosis had occurred, he believed it was due to trauma which had been produced by allowing the patient to walk upon the apparatus, or to a joint in the splint which allowed of free motion, or to traction not having been made in the axis of the neck. He considered that the introduction of the long traction splint had marked a distinct advance in orthopaedic surgery, but he thought still a further advance would follow attention to the points just mentioned, and it was on this account that he had adopted the plan of complete immobilization. The long traction splint was born of a fear of ankylosis and a desire that the patient should have exercise, yet in his own experience, which embraced a large number of dispensary cases of the worst class, ankylosis had not occurred in a single one of the cases that he had treated during the past four years. The members would doubtless recall the patients that he had previously presented, who, although completely immobilized for periods of about a year, still had complete motion of the joint. He did not believe that fixation of a joint, either diseased or healthy, resulted in ankylosis. The fact that ankylosis was not a constant result of fixation proved this theory to be erroneous. The "ossified man," during the early stages of his disease, had been subjected to all sorts of manipulations, yet every joint had become ankylosed. He believed the case of ankylosis reported in the paper was due to some affection of the nervous system, and was not the result of the immobilization. Ankylosis was determined by the character of the inflammation, its severity and duration, the parts involved, and the subsequent cicatricial contraction of the capsule of the joint, and he could not see how passive motion could prevent such destructive changes. The long traction splint, no matter how applied, would allow the foot to be elevated  $35^{\circ}$  by tilting of the band at the pelvis. He preferred this instrument, however, to the short traction splint. Although he had employed lateral traction at first without knowing that it had been used before, he had since found several references to it in literature, showing that it had been used many years ago by Busch.

While on the subject of the use of the long traction splint, he wished to call to mind the fact that cases of hip-joint disease presented great differences, and that some which ran a favorable course were accompanied by much pain, while in others which were associated with extensive destruction of bone there was very little pain. He hoped that every one using the long traction splint would have as fortunate an experience as the author had had, but for the present he felt that he must continue to use the lateral traction splint.

Dr. JOHN RIDLON said that in a paper that he had written a few years before on the subject of fixation and traction he had stated that, as he had never met with a patient who had worn the short splint, he thought this splint could not be used much in this vicinity. He wished to take this opportunity to say that since writing that paper he had seen three patients who had previously worn this splint. He had been especially interested in Dr. Sayre's statement that he had secured better results with this instrument than with the long traction splint. Some years ago he had come to the conclusion that the long traction splint was positively harmful as a walking apparatus, as it seemed to increase the "pumping action" at the joint. That it should do so seemed reasonable when one recalled the fact that with a traction of from five to ten pounds and a splint weighing from six to eight pounds the patient at each step stood upon the splint, lifting the sound leg and relaxing all traction. The effect of this upon the joint could easily be imagined when it was remembered that a child running about took two or three thousand steps an hour. That this splint did exert a harmful influence in this way seemed to be still further confirmed by the bet-

ter results that the author had obtained from the short traction splint. As many of the cases had been treated at different times by both the long and the short splint, it was difficult to say how much of the good result was to be attributed to the one or the other. It seemed to him that some patients with hip-joint disease seemed to recover, no matter what the method of treatment adopted, or even when they were entirely untreated. We had not yet found out what the essential vital principle was in the treatment of each individual case. As an instance of this he cited the case of a child whom he had treated most carefully for six years, and yet the result was not so good as in the case of a sister of this child, who had gone through the entire period of hip disease without any surgical treatment. It was true that some of his patients who should be on crutches were walking around on the limb, because he was unable to control them, yet he was free to admit that it did not seem to have hurt them.

Dr. T. HALSTED MYERS said that in the majority of cases of tubercular osteitis of the hip the primary local focus was in the neck of the femur at the junction of the epiphysis and the shaft. We could recognize this condition by appropriate tests, and, as at this stage there was no involvement of the cartilages of the joint, it was obviously unnecessary to immobilize the joint; yet it was most important that concussion and pressure should be taken from the inflamed and softened bone, and that there should be no possibility of the weight of the body being thrown on that limb. He believed that in a number of cases the disease never extended beyond this location, and was cured *in situ*. He had no pathological specimens to prove this point, and it had not been investigated as yet; he spoke from a clinical standpoint. In cases where there was erosion of the joint surfaces bearing against each other he thought motion was injurious, as well as pressure, as was plainly indicated by the presence of reflex muscular spasm, which was a reliable guide. We always found reflex muscular spasm at the point where motion was injurious. On the other hand, immobilization of a disorganized joint, provided pressure was also relieved, he had never seen cause any permanent injury to the joint. To show the importance of the relief of pressure in this connection, he stated that, in order to relieve pain, he had had to apply traction to a patient with hip disease who was wearing a Thomas splint correctly shaped and applied. Recognizing the importance of this evidence, he had made repeated careful observations, but always with the same result—that traction was in this case necessary for the relief of pain.

Dr. H. W. BERG wished to protest against the feeling of nihilism that might be engendered by Dr. Ridlon's remarks. If we were able to make a purely pathological diagnosis instead of a generic one—"hip disease"—we might be able to point out in advance those cases which would do well and those which would do ill.

Dr. W. R. TOWNSEND said that, while not wishing to detract in the least from the credit due the author for securing such excellent results, he desired to point out the fact that one factor contributing to this end had undoubtedly been the very favorable surroundings of his patients. Again, the author could hardly have selected better cases had he desired to illustrate the traumatic origin of hip disease, and the fact of many of the cases reported having had such an origin afforded still another reason for the excellence of his results. Bone tuberculosis and osteitis due to traumatism might give the same clinical symptoms, but they should give different ultimate results.

Dr. JUDSON said that for a number of years he had kept a description of all the hip splints he had applied, and their weight had ranged from a pound and a half in the case of a child to a little over five pounds for a large adult. He thought that some

of us were dissatisfied with the hip splint because we expected more than the nature of these cases allowed of. We could not cut short hip disease as we could break up chills with quinine. We must put the part and the system in the most favorable position attainable, and then wait for the natural processes of repair. This was best done by making traction so long as it is needed, and protecting the limb throughout the treatment from the traumatism of walking, while locomotion was freely practiced. Traction and protection were the features of the American method by which it was distinguished from the Liverpool method of portable leverage and the London method of recumbent traction. The results obtained by Dr. Sayre had been good, but not exceptional. They were within the reach of all who adhered to the plan of treatment that had been outlined.

Dr. R. H. SAYRE said that the fact that one man regarded a case as tubercular, and another as non-tubercular, did not change the character of the lesion, or influence the progress of the disease. Regarding the question of the occurrence of ankylosis, he believed that some cases would end in ankylosis whether motion was allowed or entirely prevented, and, as an illustration of this, he recalled a case of double hip-joint disease in which the disease on one side was very severe and was accompanied by extensive suppuration, while on the other side it ran a much milder course. During the progress of the disease in the latter joint the patient had been kept in bed or in a wire cuirass; yet, notwithstanding this treatment and the apparently mild course of the disease, absolute ankylosis had been the result, while in the other joint good motion had been secured. Again, after the disease had apparently been arrested in both joints, and both seemed to be equally stiff, passive motion had given a good joint on the side that had supplicated, but had resulted in no benefit to the other side. He had seen a number of cases of disease of both hips and knees in which the joints had seemed to be perfectly fixed until passive motion was instituted. He did not approve of leaving these stiffened joints to be loosened by the ordinary motions which the patient would make.

Dr. PHELPS agreed with the other speakers as to the value of forcible breaking up of adhesions under anæsthesia, but he could not understand how motion of a joint during inflammation could prevent ankylosis. As the inflammatory material which limited the motion during inflammation was absorbed, there would be an increased motion of the joint, and, in his opinion, active motion on the part of the patient was better than passive motion. He had frequently produced by passive motion a return of the pain and stiffness in the joint.

Dr. TOWNSEND could not see how any one could believe that an osteitis due to traumatism represented the same pathological process as one due to tuberculous, although the clinical symptoms might be identical.

The CHAIRMAN said that, while everybody must admit that the statistics presented in the paper were not only brilliant, but exceedingly valuable, in comparing them with the statistics of those who did not resort to excision of joints, allowance must be made for those joints which had gone on to excision. This would also affect the mortality. One point which had been very strongly brought out in the paper was the positive, decided, and immediate relief from pain obtained in the majority of cases by traction properly applied. In hip-joint disease it was fair to infer, as was also evident from the results obtained, that, if the pain was relieved, the treatment was beneficial to the joint. He believed in immobilization in the acute stage, so far as it could be produced by traction, but he did not believe it was necessary to go up to the axilla and immobilize the spinal column. Sometimes traction must be supplemented by recumbency and sometimes by the use of

crutches; these were all the necessary elements for the proper management of those cases which could be successfully treated by mechanical means. His own experience had led him to think that by far the most efficient method of applying traction was by means of the long traction splint.

Dr. L. A. SAYRE said that the statistics presented were only those which had been fully completed, and they represented forty years of work. He thought Dr. Phelps had misunderstood him about the question of motion at the joint. He had always advocated, repeatedly and persistently, rest of an inflamed joint, but he permitted such motion as the patient would himself make. He did not consider that any motion which would not cause pain was injurious. He applied sufficient traction to prevent pressure on the joint, and it was all-important that this traction should be made in the proper direction. He did not approve of an unyielding strap, which, in the splint used by Dr. Taylor and Dr. Shaffer, was attached to the pelvic band and to the shaft of the splint; in his opinion, it should be made of elastic webbing. As regarded the ætiology of his cases, he did not pretend to say whether or not the processes had been tubercular or non-tubercular. At the time he began his investigations everything was called "serofula," and medical men believed that tubercle was always found in the lungs before it was deposited in other parts of the body. Having learned from autopsies in some cases of hip-joint disease that there were no tubercles in the lungs, he had begun to doubt the tubercular nature of this disease, and he had been led to look upon it as a chronic inflammation resulting from a greater or lesser degree of traumatism. Now that the presence of the tubercle bacilli furnished a definite basis for a diagnosis, he was trying to learn something about the occurrence of tubercle in these cases. Clinical experience had taught him, however, that, whether they were tubercular or not, fresh air, good food, and freedom from pain were the essentials for a cure. Referring to the occurrence of ankylosis, he said that one single case of absolute, firm ankylosis of all the joints in the body was worth more to him than any number of experiments on dogs. In the case which he had reported in his paper there had been no fever, no evidence of any nervous derangement—in fact, no constitutional disturbance. To apply a splint without traction was wrong; nothing made better immobilization than plaster of Paris, and it was much more comfortable than the Thomas brace; yet it was insufficient without traction to overcome the reflex muscular contraction and to relieve pain. The treatment that he advocated was the best possible one, no matter what the ætiology of the disease.

Dr. JOHN RIDLOX exhibited a convenient pocket knife with blades especially designed to facilitate the removal of plaster-of-Paris bandages.

## Book Notices.

*The Principles and Practice of Medicine.* Designed for the Use of Practitioners and Students of Medicine. By WILLIAM OSLER, M. D., Fellow of the Royal College of Physicians, London, etc. New York: D. Appleton & Company, 1892.

WITH a dedication to certain of his teachers, a brief note acknowledging obligations to some of his associates, a sentence from the first aphorism of Hippocrates, and a less familiar quotation from Plato, the author starts *in medias res* with his first section, on the specific infectious diseases. And this brevity of expression, this absence of padding of introduction, of padding of text, is a characteristic of the work. With the many well-

known and popular text-books on the theory and practice of medicine demanding the consideration and patronage of the profession, the author must have felt that the discoveries in pathology and the improvements in methods of treating disease, as well as the addition to our nosology of new diseases that are not described in the familiar text-books, offered a sphere of usefulness for a work that would present the latest knowledge on these topics. The medical profession will, we believe, look upon this expectation as well founded, and give the volume a cordial and deserved welcome.

A feature of the work that impresses one is the credit given to discoverers and original workers. In the first article, that on typhoid fever, one notes with pleasure the tribute to the work of Gerhard, the Jacksons, Bartlett, and Shattuck for their quick recognition of Louis's distinction between typhus and typhoid fever, and their labors in formulating the essential clinical and pathological features of these diseases; while on a following page Eberth's, Koch's, and Goffky's work in experimenting with the specific micro-organisms is concisely considered, and reference is made to Brieger's typhotoxine and toxalbumin. So, in treatment, no effort is made to insist upon the adoption of recent innovations because they are new; for example, in typhoid fever the advantages of the so-called Brand method are referred to, and the author says that "a majority of our patients complain of it bitterly, and in private practice it is scarcely feasible."

Sufficient weight is given to the utility of Laveran's discovery of the hæmatozoon of malarial fever; and it is true that the entire group of diseases included under the terms remittent, bilious remittent, typho-malarial, and pernicious malarial fever, as well as malarial hæmaturia, should be studied anew in the light of these observations. To many might be commended the axiom that an "intermittent fever which resists quinine is not malarial."

The chapter on tuberculosis is very thorough in its survey of the light that has recently been thrown on the varied manifestations of this disease. Under the question of prognosis, rather than prophylaxis, the question of marriage of persons who have had tuberculosis is briefly considered. It is stated that subjects with healed lymphatic or bone tuberculosis marry occasionally with personal impunity, and may beget healthy children, and conceding that in such families scrofula, caries, arthritis, and cerebral and pulmonary tuberculosis are more common, and it is considered that the risks are such as may properly be taken. In regard to arrested or cured pulmonary tuberculosis the author speaks more decidedly on the subject.

The second section is devoted to the constitutional diseases, the various forms of rheumatism, gout, diabetes, rickets, scurvy, purpura, and hæmophilia. In the third section, on the diseases of the digestive system, in the chapter on typhlitis, we note that the onus is thrown on the physician to say whether the case is suitable for an operation, and when the operation should be performed.

The fourth section treats of diseases of the respiratory system and of the mediastinum; the fifth, of diseases of the circulatory system; the sixth, of diseases of the blood and ductless glands; the seventh, of diseases of the kidney; the eighth, of diseases of the nervous system; the ninth, of diseases of the muscles; the tenth, of the intoxications, sun-stroke, and obesity; and the eleventh, of diseases due to animal parasites. It would be impracticable to refer to the various chapters in these sections, but we have not been impressed that any needful matter has been omitted; and we have been struck with the care with which many of the rarer varieties of disease have been considered. At first reading this might impress one as a rather sketchy manner of disposing of a subject, and yet on

second thought it will be noticed that no established fact in ætiology, pathology, or symptomatology is lacking; and were not this conciseness exhibited the work would be swelled to double its present dimensions.

The author is not a therapeutic optimist, and his remarks on treatment assume a modicum of intelligence on the part of his reader. In regard to some diseases—such as Weil's disease, mountain fever, myxædema, myotonia congenita, and paramyoclonus multiplex—no suggestions of treatment are made; and it seems to be true that no satisfactory treatment is known for such cases.

A word of commendation for the excellence of the indexing is deserved; nothing seems to have escaped the indexer.

It is an excellent text-book, and is sure to be accorded a generous welcome.

*Traitement des maladies de la peau.* Avec un abrégé de la symptomatologie, du diagnostic et de l'étiologie des dermatoses. Par le Dr. L. Brocq, médecin des hôpitaux de Paris. Deuxième édition, corrigée et augmentée. Paris: Octave Doin, 1892.

In the first edition of this work the author stated that his desire was to popularize the treatment of diseases of the skin, and so satisfactorily has he accomplished this object that his first edition of his work has been exhausted in eighteen months. In that short period the progress of dermatology has not been characterized by any particularly novel discoveries; still our author has incorporated into his text whatever there is new that is of value. For instance, certain diseases of the mucous membrane that have been by tacit consent transferred to the domain of the dermatologist are included in this edition; such, for example, as leucoplasia, leucokeratosis, black tongue, marginal exfoliative glossitis, aphthous and contagious inflammation of the vulva, etc.

Additions have been made in the articles on actinomycosis, glanders, pyocyanic disease, the parakeratoses, the ætiology of eczema, seborrhœic eczema, and lichenoid eruptions. The pharmacological portion of the volume has been revised by M. Portes, of the St.-Louis Hospital.

The alphabetical arrangement of diseases and the very complete index—a rare feature in many foreign medical works—make this a very convenient volume of reference, both for the specialist and for the general practitioner.

*A Manual of Autopsies.* Designed for the use of Hospitals for the Insane and other Public Institutions. By I. W. BLACKBURN, M. D., Pathologist to the Government Hospital for the Insane, Washington, D. C. Illustrated. Philadelphia: P. Blakiston, Son, & Co., 1892.

This little work will be found of great value by those physicians in general as well as hospital practice who have to make their own necropsies.

The matter is compactly arranged, and the portion of the work devoted to the examination of the brain is comprehensive and illustrated by numerous plates.

The volume was prepared at the request of the Association of Superintendents of American Institutions for the Insane, and is published with their indorsement.

*The Age of the Domestic Animals,* being a Complete Treatise on the Dentition of the Horse, Ox, Sheep, Hog, and Dog, and on the Various other Means of determining the Age of these Animals. By RUSH SUIPPEN HUIDEKOPER, M. D., Veterinarian (Alfort, France), Professor of Sanitary Medicine and Veterinary Jurisprudence, American Veterinary

College, New York, etc. Illustrated with Two Hundred Engravings. Philadelphia and London: F. A. Davis, 1891. 8vo. Pp. viii-217.

This book is a well-written and well-arranged treatise upon an important subject. It is a valuable work for all who have to do with the animals considered. It is illustrated fairly well, and is fully indexed.

*Human Monstrosities.* By BARTON COOKE HIRST, M. D., Professor of Obstetrics in the University of Pennsylvania, and GEORGE A. PIERSOL, M. D., Professor of Histology and Embryology in the University of Pennsylvania. Part II. Illustrated with Thirteen Photographic Reproductions and Twenty-five Woodcuts. Philadelphia: Lea Brothers & Co., 1892.

In the second part of this work, the first part of which was reviewed in the *Journal* for January 23d, the authors consider the classes of Celosoma, Exencephalus, Pseudencephalus, and Anencephalus. The six varieties of eventration described by Isidore Geoffroy Saint-Hilaire, aspalasoma, agenosoma, cyllsoma, schistosoma, pleurosoma, and celosoma, are described and illustrated. The subdivisions of exencephalus into notencephalus, proencephalus, podencephalus, hyperencephalus, iniencephalus, and exencephalus are well described, and each variety is illustrated.

The thirteen plates of photo-electrotypes and the twenty-five woodcuts are as excellent as in the former volume, and the general high character of the work is maintained.

*Atlas of Clinical Medicine.* By BYROM BRAMWELL, M. D., F. R. C. P. Edin., F. R. S. Edin., Assistant Physician to the Edinburgh Royal Infirmary. Vol. I. Part III. Edinburgh: T. & A. Constable, 1891.

THE third Fasciculus of this admirable work maintains the high standard of excellence attained by the first two parts. It contains ten plates and articles on progressive unilateral atrophy of the face, chronic progressive bulbar paralysis, ophthalmoplegia, molluscum fibrosum, and xeroderma pigmentosum. Though the plates are the most marked feature of the work, the text is worthy of the highest praise, presenting as it does substantially all that is known of each disease. Every article is virtually a clinical lecture of the most practical kind, designed not only for the student, but for the general practitioner of medicine.

#### BOOKS, ETC., RECEIVED.

Technique d'électrophysiologie. Par le Dr. G. Weiss, Ingénieur des ponts et chaussées, Professeur agrégé à la Faculté de Médecine de Paris. Avant-propos de M. le Professeur Gariel. Paris: Gauthier-Villars & fils; G. Masson. Pp. 214.

Maladies des organes respiratoires; méthodes d'exploration; signes physiques. Par Léon Faisans, médecin de la Pitié. Paris: Gauthier-Villars & fils; G. Masson. Pp. 192.

Gynécologie. Séméiologie génitale. Par A. Anvard, Accoucheur des hôpitaux. Paris: Gauthier-Villars & fils; G. Masson. Pp. 175.

### SCISSORS FOR THE REMOVAL OF SUTURES.

By JOHN A. PRINCE, M. D.,  
SPRINGFIELD, ILL.

SCISSORS exclusively for the removal of sutures may seem a superfluous article in a surgeon's armamentarium, already necessarily large, but I trust upon trial the verdict may be different.

There exists no instrument whereby the removal of ordinary and especially of fine coaptation sutures may be done easily and without pain and annoyance to the patient, who usually dreads the removal of the sutures almost as much as the original operation, and with reason. In the removal of a suture it is of course necessary to cut the loop, and, to facilitate the entrance of the point of the scissors for this pur-

pose, more or less tension is put upon it, thus causing pain. Some time ago I began to use Stevens's tenotomy scissors for this purpose, and was surprised to find how easily and painlessly a suture could be removed.

Deriving my idea from his instrument, I have had Messrs. Tiemann & Company construct for me the scissors shown in the accompanying cut. The cutting edge is limited to the tapering extremity of three eighths of an inch.

These scissors are made very strong and are capable of cutting heavy silk or silver wire, yet they possess a cutting point as fine as the most delicate eye scissors. Hence, in the removal of a suture by them, the slightest degree of tension is necessary, and the minimum of pain is felt.

## Miscellany.

**Ocean Holidays.**—The following appeared as an editorial article in the *British Medical Journal* for April 9th:

The advantages of ocean travel as a means of repose and restoration to those overwrought by the wear and tear of political, commercial, and literary life have been illustrated in the columns of the *British Medical Journal* for many years. They are every year more fully admitted and more widely taken advantage of. The sense of motion beguiles what might otherwise be the tedium of ship-board life—the quiet routine, the absence of daily responsibilities, the new subjects of consideration; the salt air, the constantly renewed draughts of oxygen, the conditions of healthy exercise without fatigue, and the irresistible charms of contact with the most sublime aspects of Nature are all influences which act as a mental and bodily tonic. They are re-enforced by change of scene, transplantation to new countries and genial climates, and the observation of races, countries, and cities, which never fail to arouse new feelings of interest in those who behold them for the first time. The facilities for such ocean trips are now greatly multiplied. The Peninsular and Oriental Company's steamers, which girdle the world, are specially laid out now for the comfortable, and even luxurious, accommodation of travelers in search of health and recreation—and the human interests and physical and mental needs of such travelers are carefully con-

sidered in every way. Circular tours and holiday trips are to be had to most parts of the world, and at the seasons best suited to enable the traveler to benefit by the most healthy seasons in each country. Other lines follow the example. Ocean yachts facilitate shorter and well-planned holidays, so that it is becoming as common now to take a winter holiday in Egypt or India, in Madeira or the Canaries, as formerly to any part of the continent of Europe. Moreover, as the fatigue of traveling by sea is far less than that of traveling by land, as the movement of an ocean steamer generally soon ceases to cause discomfort, even to the qualmish, and as the cost is far less, while the comfort and luxury are greater, "holidays at sea" prove attractive to a vastly increased and increasing proportion of our population.

But there is a risk, and, indeed, more than a risk, of the enormous advantages of such a relief from the wear and tear of modern life being lessened for the invalid and the convalescent by an abuse of the very facilities which the new development of sea travel offers. The traveler for health, the invalid with weakened nerve power, is tempted, perhaps too often, to follow in the rapid footsteps of the ardent "globe trotter." It is so easy nowadays to do a great deal without fatigue that the temptation to do too much is not avoided. When formerly the patient with delicate lungs would find his way to Cairo or Luxor, or slowly ascend the Nile in a dahabeah, he now pushes on to India, traverses the whole continent, and returns in three or four months. If he stays in Egypt he steams up the Nile, and having "done" Philæ and the Cataracts, returns to balls and parties and the theatres of the now gay and Europeanized capital in Cairo; he gets neither the rest nor the healthy, quiet Oriental life which formerly soothed his nerves, interested his mind, and invigorated his health. The rush of travelers through Egypt is a thing to be admired and approved in itself, for the contact with our dependencies and the personal observation of social conditions in the East add largely to our intelligence and sympathy as a governing nation. But the invalid will do wisely to differentiate himself from the globe trotter. A winter in India or in Egypt or the Atlantic islands offers a vista of escape from fogs and cutting winds, a substitution of sunlight and landscape, cloudless sky, warm airs, of brilliant color, and fantastic life which may well and wisely tempt the weary and the overworked to follow the sun in search of health and of the sense of a larger life than can be lived in the routine of daily work in the centers of industry here or in the restricted formal circles of the winter health resorts of Europe, delightful as they are. But the holiday in the East, like the holiday in the Riviera, or Madeira, or Teneriffe, must be one of long periods of rest and not of continuous movement. The longer the sea voyage and the less the land travel the more restorative such a holiday is likely to be where broken health is the cause of the journey.

A medical correspondent, Mr. Hope Lewis, medical officer at Auckland, recently wrote to us saying that he had met with a number of patients on their way through New Zealand, where they were half-way round the world. Among them all sorts of cases presented themselves—phthisical, rheumatoid, gouty, nervous, spinal—and in all stages. They were not by any means all benefited. "Rush," he complains, "is the axiom now."

The old-fashioned sailing vessel is now almost a thing of the past for this route. It has more than once occurred to him that a patient suffering from nervous breakdown has inquired as to a course at the thermal district of Rotorua, but the answer to the question how long a stay was proposed in the colony has been that the Orient steamer was due at Lyttelton in three weeks, and must be "caught." Such a patient had left England two months before, spent a few days in Sydney and Melbourne, and come straight on to New Zealand, where he had just arrived. This is good traveling for a hale and hearty man, but is not the sort of thing an invalid should take in hand, although there is reason to know that many undertake it, keeping up diaries and diligent note-taking all the time, and going wherever materials may be accumulated for the inevitable "book of travels." Easy and fascinating as is life on board a great ocean steamer, invalids should be cautioned not to enter too freely on the amusements which are provided for the young, strong, and active. "Round the world in eighty days" is a possible achievement nowadays, but it is the opposite of what the rest-seeker should hold in view.

The whole world is now open to the doctor who prescribes and to

the invalid who seeks ocean holidays, the best climates, the most glorious natural scenery, the most perfect mountain solitudes, or the most picturesque populations among which to repose and recruit. But it is well to choose one or two items in the large bill of fare. The Rocky Mountains of Canada are now rendered so accessible by the Canadian Pacific Railway, with its palace cars and traveling *table d'hôte*, that without fatigue and without effort the marvelous glaciers—one of which would swallow up all the glaciers of Switzerland—its rivers, packed with salmon, and its primeval forests, may be reached in a few days. Even Japan in the Far East, the most attractive play-ground of the world, is little more than a month away from our doors. The spice gardens of Ceylon, the fairy palaces of India, the temples and deserts of Egypt, may all be reached with less fatigue than was formerly involved in a tour in many parts of Europe; while it is as easy to get to Madeira or Teneriffe as to go by sea to Glasgow, and much more comfortable; and the few weeks which we were all used to spend at a dull seaside place may now, thanks to the facilities of ocean travel, be spent far more delightfully, and as a short winter holiday, say, in Malta, Gibraltar, or Tangier, without any fatigue, and with singular refreshment of mind and body. The hints which we have from more than one correspondent as to the tendency to hurry away from one town to another, and from continent to continent, prompt us to caution both doctors and patients that it is easy to spoil the value of holidays at sea, and health tours generally, by extending them to meet time requirements for much sight-seeing, and by confounding health and rest trips with "globe trotting," which is the privilege of the healthy and the curious. The most perfect of all holidays are to the Far East, but enough time must be given, and as much steamer put in and as little railway travel as possible.

**The "Ginger-beer Plant."**—In the *Proceedings of the Royal Society* we find the following abstract of a communication by H. Marshall Ward, M. A., F. R. S., etc.: The author has been engaged for some time in the investigation of a remarkable compound organism found in home-made ginger-beer fermentations.

It occurs as jelly-like, semi-transparent, yellowish-white masses, aggregated into brain-like clumps, or forming deposits at the bottom of the fermentations, and presents resemblances to the so-called *Kephir* grains of the Caucasus, with which, however, it is by no means identical.

He finds that it consists essentially of a symbiotic association of a specific *saccharomycete* and a *schizomycete*, morphologically comparable to a lichen, but, as met with naturally, invariably has other species of yeasts, bacteria, and mold-fungi casually associated with these. He has successfully undertaken the separation of the various forms, and groups them as follows:

1. The essential organisms are a yeast, which turns out to be a new species allied to *Saccharomyces ellipsoideus* (Reess and Hansen), and which he proposes to call *S. pyriformis*; and a bacterium, also new and of a new type, and named by him *Bacterium vermiforme*.

2. Two other forms were met with in all the other specimens (from various parts of the country and from America) examined—*Mycoderma cerevisie* (Desm.) and *Bacterium acti* (Kützing and Zopf).

3. As foreign intruders, more or less commonly occurring in the various specimens examined, were the following:

*a.* A pink or rosy yeast-like form—*Cryptococcus glutinis* (Fresenius)?

*β.* A small white aerobic top-yeast, with peculiar characters, and not identified with any known form.

*γ.* The ordinary beer-yeast—*Saccharomyces cerevisie* (Mayen and Hansen).

*δ.* Three, or probably four, unknown yeasts of rare occurrence.

*ε.* A bacillus which forms spores and liquefies gelatin with a greenish tinge.

*ζ.* A large spore-forming bacillus, which also liquefies gelatin.

*η* and *θ.* Two—perhaps three—other *schizomycetes* not identified.

*ι.* A large yeast-like form which grows into a mycelium, and turns out to be *Oidium lactis* (Fresenius).

*κ.* A common blue mold—*Penicillium glaucum* (Link).

*λ.* A brown "torula"-like form, which turns out to be *Dematium p. ulmans* (De Bary).

$\mu$ . One, or perhaps several, species of "*Torula*" of unknown origin and fates.

Of these forms, the author has succeeded in cultivating and examining very thoroughly all but those under  $\theta$  and  $\mu$  in the foregoing list.

*Saccharomyces pyriformis* (n. sp.) is a remarkably anaerobic bottom-yeast, forming spores, and developing large quantities of carbon dioxide, but forming little alcohol. It has also an aerobic form—veil form of Hansen—in which the rounded cells grow out into club-shaped or pyriform cells, whence the proposed specific name. It inverts cane sugar and ferments the products; but it is unable to ferment milk sugar. It forms rounded, morula-like, white colonies in gelatin, and the author has separated pure cultures from these. He has also studied the development and germination of the spores which are formed in twenty-four to forty-eight hours at suitable temperatures on porous earthenware blocks. They also develop on gelatin. The technological characters have been kindly determined and confirmed for the author by Mr. Horace Brown, F. R. S., and Dr. Morris, of Burton-on-Trent.

The specific *schizomyete* (*Bacterium vermiforme*, n. sp.) has been very fully studied by the author. It occurs in the fermentations as rodlets or filaments, curved or straight, incased in a remarkably thick, firm, gelatinous sheath, and is pronouncedly anaerobic, so much so that the best results are got by cultivating it in carbon dioxide under pressure.

The sheathed filaments are so like worms that the name proposed for the species is appropriately derived from this character.

It will not grow on gelatin, and separation cultures had to be made in saccharine liquids by the dilution methods.

It grows best on solutions of beet root or of cane sugar, with relatively large quantities of nitrogenous organic matter—*e. g.*, bouillon, asparagin, and tartaric acid. Good results were obtained with mixtures of Pasteur's solution and bouillon.

The author has found that the bacterium into which the filaments subsequently break up can escape from its sheath and become free, in which state it divides rapidly, like ordinary bacteria. Eventually all the forms—filaments, long rods, short rodlets—break up into cocci. No spores have been observed. These changes are dependent especially on the nutritive medium, but are also affected by the gaseous environment and the temperature. The jelly-like clumps of the so-called "ginger-beer plant" are essentially composed of these sheathed and coiled *schizomyetes*, entangling the cells of *Saccharomyces pyriformis*. But the action of the *schizomyete* alone on the saccharine medium differs from that exerted by the latter alone. This was proved by cultivating each separately, and also by cultivations in which, while each organism was submerged in the same fermentable medium, they were separated by permeable porcelain (Chamberland filters), through which neither could pass.

The author has also constructed the "ginger-beer plant" by mixing pure cultures of the above two organisms; the *schizomyete* entangled the yeast cells in its gelatinous coils, and the synthesized compound organism behaved as the specimens not analyzed into their constituents.

Some very curious phenomena in connection with the formation of the gelatinous sheaths and the escape of the bacteria from them were observed in hanging-drop cultures, and are figured and described by the author. The conditions for the development of the gelatinous sheaths, and therefore of the coherent brain-like masses of the *schizomyete*, are a saccharine acid medium and absence of oxygen. The process occurs best in carbon dioxide; it is suppressed in bouillon and in neutral solutions in hydrogen, though the organism grows in the free, non-sheathed, motile form under these conditions.

The behavior of the pure cultures of the bacteria, in as complete a vacuum as could be produced by a good mercury-pump, worked daily and even several times a day for several weeks, is also noteworthy. The author records his thanks to his friend and colleague, Professor McLeod, for much assistance in regard to this apparatus. The development of the sheaths is apparently indefinitely postponed *in vacuo*, but the organism increased, and each time the pump was set going an appreciable quantity of carbon dioxide was obtained. In vacuum tubes the same gas was evolved, and eventually obtained a pressure sufficient to burst some of the tubes. The quantity of carbon dioxide evolved

daily by the action of the bacterium alone, however, is small compared with that disengaged when the organism is working in concert with the symbiotic yeast; in the latter case the pressure of the gas became so dangerous that the author had to abandon the use of sealed tubes.

The products of the fermentation due to the *schizomyete* have not yet been fully determined in detail; lactic acid or some allied compound seems to be the chief result, but there are probably other bodies as well.

The author owes acknowledgment to Dr. Matthews, of Cooper's Hill, for advice and assistance in examining the products of these fermentations.

The pink yeast-like form proved to be very interesting. It has nothing to do with the "ginger-beer plant" proper, though it was invariably met with as a foreign intruder in the specimens. The author identifies it with a form described by Hansen in 1879;\* unfortunately, the original is in Danish, but the figures are so good that little doubt is entertained as to its identity. It is also probably the same as Fresenius's *Cryptococcus glutinis* in one of its forms. It is not a *saccharomyete*, and does not ferment like a yeast; it is aerobic.

The chief discovery of interest was that in hanging drops the author traced the evolution of this "rose-yeast" into a large, complex mycelium, bearing conidia, and so like some of the *basidiomyetes* that it may almost certainly be regarded as a degraded or "torula" stage of one of those higher fungi. Full descriptions and figures are given by the author.

The form *Mycoderma cerevisiæ* was thoroughly examined. The author's results confirm what is known as to its aerobic characters. Statements as to its identity with *Oidium lactis* were not only not confirmed, but the author grew these two forms side by side, and maintains their distinctness. Nor could he obtain spores in this fungus, thus failing to confirm earlier statements to the contrary. He regards it as probable that oil drops have been mistaken for spores; he also finds that in later stages of fermentation by this organism a strong oily smelling body is produced.

With regard to *Bacterium acti*, the author has little new to add. A point of some interest was the repeated production of acetic ether, which scented the laboratory when this *schizomyete* was growing in company with the small white aerobic top-yeast referred to under ( $\beta$ ). As this phenomenon was found to have nothing to do with the question being investigated, the author did not pursue it further. It seemed probable, however, that the yeast produced alcohol, which the *schizomyete*, in presence of oxygen, partially oxidized, and that the fragrant ether was produced by interaction of the products.

With regard to the other forms found, the author was chiefly concerned with testing their relations to the important and essential organisms. It need only be remarked here that the hanging-drop cultures of *Dematium pullulans* were very successful, and that some of the molds and at least one *bacillus* (of which the spore formation, etc., were traced also) were traced to ginger used in the manufacture of the well-known beverage.

The author hopes very shortly to have the honor to lay before the society a full account of his research, of which the above is only a brief notice. The fuller account will contain detailed descriptions, as well as figures, of the apparatus, mode of culture, etc.

**The Association of Medical Superintendents of American Institutions for the Insane.**—The forty-sixth annual meeting will be held in Washington, at the Arlington Hotel, on the 3d, 4th, 5th, and 6th of May, under the presidency of Dr. Daniel Clark, of Toronto, Ontario.

**The American Electro-therapeutic Association** will hold its second annual meeting in New York, at the Academy of Medicine, on October 4th, 5th, and 6th, under the presidency of Dr. W. J. Morton.

**The late Dr. Henry I. Bowditch, of Boston.**—The *Edinburgh Medical Journal*, in its April number, prints the following obituary notice of Dr. Bowditch, written by Dr. W. T. Gairdner:

Although the number of those who made the acquaintance of this distinguished physician on his visit to this country in 1861 must now be sadly diminished, it may be permitted to us in this journal to offer

\* *Organismer i Æl og Ælurt*. Copenhagen, 1879.

a brief tribute to his memory, from one who is perhaps the only hospital physician now in a position to do so among those who gave a hearty greeting to Dr. Bowditch in the Edinburgh Royal Infirmary more than thirty years ago. The writer was thoroughly attracted at that time, not only by what appeared to him an eminently noble personality, but also by the narrative of successful results in the treatment of pleuritic effusions by the method of what was then called *suction*,\* although under the more pretentious name of *aspiration* it came, many years later, to be made a *boom* in Paris without the slightest reference to the first employment of the method in America. Dr. Bowditch was even then, although in the prime of life and vigor, by no means a young man, and the steady, persistent, and indeed brilliant work he had done in connection with this subject deserved a better fate than to be lost sight of amid the struggles for *éclat* of a young French hospital physician not at all careful as to what had been done before him. Dr. Bowditch made converts in Edinburgh in those days, and at least two of the hospital staff began to use thoracentesis by suction from that time onward. One of the two is the writer of these lines, and Dr. Bowditch has been known to say that Dr. Budd, of King's College, London, and the present writer were the first in this country to adopt the improved procedure. But Dr. Bowditch, though a most eminent thoracentesist, was far more than this. He was a most admirable and cultured physician in all respects, and not only showed in diagnosis and in treatment a wide and well-ordered knowledge and a cultivated judgment, but he appreciated also, as comparatively few then did, the importance of the preventive service of humanity in its relations to the curative. The researches which he first brought before the public in 1862 † into the connection of moisture in subsoils, and the effect of drainage, or the want of it, on the local distribution of phthisis in Massachusetts, became stimulus to further fruitful researches, which in England were undertaken at the instance of the medical officer of the Privy Council, by Dr. George Buchanan, of London, now the chief of the medical service under the Local Government Board. ‡ Had Dr. Bowditch done nothing else but these two things, his merit would still have been great; but in fact his was a most busy and valuable life, from many different points of view. He was greatly trusted as a physician in Boston, and was a personal friend of all of the many celebrities of the New England city; he was a successful teacher and hospital physician, and for some time Medical Officer of Health to the State Board of Massachusetts; he was, moreover, a cultured and most appreciative member of society in the most literary and scientific atmosphere on the American continent; and, lastly, he was an enthusiast for freedom and justice, and as such, an abolitionist as regards slavery, at a time when to be an abolitionist out and out required courage and convictions of a very high order. Add to this that he was one of those men whose character is transparent, and who could not if he would have done and said anything but what was the outcome of an honest and fearless nature, and it will be easily under-

\* Dr. Bowditch always attributed the invention of this method and the appropriate instrument to Dr. Morill Wyman, of Cambridge, Mass., who performed his first thoracentesis by suction in 1850. But neither Dr. Wyman nor Dr. Bowditch seem to have cared to put in a claim of priority, although, at the date of a most interesting and lucid letter to the author of this notice, bearing date May 22, 1862, no fewer than 160 operations had been performed upon 85 persons, and with remarkably favorable results. See *Clinical Medicine: Observations recorded at the Bedside, with Commentaries*. Edinburgh: Edmonston & Douglas, 1862, Appendix, p. 717. Dieulafoy's first publication on the method of aspiration appears to have been in 1870.

† In an address delivered at the annual meeting of the Massachusetts Medical Society, founded on the written statements of physicians in 183 townships, republished in 1868 under the title *Consumption in New England and Elsewhere; or, Soil Moisture One of the Chief Causes*.

‡ In this instance it is satisfactory to be able to state that Dr. Bowditch's priority and merits received full acknowledgment. See the *Tenth Report (1867) of the Medical Officer of the Privy Council* (Mr., now Sir John, Simon), pp. 16, 17; Dr. Buchanan's report being in the appendix to the same volume, published in 1868.

stood that Dr. Bowditch, in his long life of over eighty years, must have left one of those memories of which Boston and America are justly proud. The author of these lines experienced only one cause of deep regret in a recent visit to the United States: that it was not permitted to him again to grasp the hand of one with whom an unbroken friendship, maintained mostly by correspondence, had deepened into love and reverence as the years advanced. The attachment and the expectation were equal on each side, but the frail tenement of clay and the failing mental powers of the veteran seemed to his nearest and dearest friends to be unequal to a satisfactory interview; and a letter, most pathetic alike in its simplicity and its kindness, announced to the visitor the anxious though forbidden desire, and the hope that "somewhere and somehow" it might be possible to resume an intercourse which was likely to be broken off only too soon on this side the grave. Dr. Bowditch died, full of years and honors, at Boston, on the 14th of January last, in the eighty-fourth year of his age. His English wife had predeceased him. One son, Dr. Vincent Y. Bowditch, is in the practice of his father's profession in Boston. The civil war cost him another son, killed while leading a squadron of cavalry. A brother's son, Dr. Henry I. Bowditch, is well known as the professor of physiology in the Harvard Medical School.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

THE INFLICTION OF THE DEATH PENALTY BY MEANS OF ELECTRICITY.

BEING A REPORT OF SEVEN CASES.

*With Remarks on the Methods of Application and the Gross and Microscopical Effects of Electrical Currents of Lethal Energy on the Human Subject.\**

By CARLOS F. MACDONALD, M. D.,

PRESIDENT OF THE NEW YORK STATE COMMISSION IN LUNACY;  
PROFESSOR OF MENTAL DISEASES IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE,  
LECTURER ON INSANITY IN THE ALBANY MEDICAL COLLEGE.

THE widespread interest manifested by the general public in the new method of inflicting the death penalty by means of electricity, and the interest which medical science would naturally be expected to feel in the humane and scientific aspects of the subject, especially with reference to the absence of conscious suffering, and the changes, if any, in the tissues and organs of the human body resulting from the passage through it of electrical currents of lethal energy, together with the fact that this method of executing criminals may now be said to have practically passed beyond the experimental stage, would seem to justify, if not indeed to demand, the presentation of an authentic summary of the practical results thus far obtained by some one whose data and conclusions would be derived from actual observation and experience in the application of the statute. The fact that the writer happens to be the only physician who has participated in all of the official preliminary experimental tests of apparatus, and witnessed all of the executions thus far had under the new law—not, however, from any zealous interest in the subject, nor even inclination to be present, but in obedience to the expressed desire of the chief executive of the State and other official superiors—furnishes the only excuse he would offer for undertaking what otherwise might well be regarded as an undesirable task.

In view of the wide publication of distorted and sensational accounts of the Kemmler execution, and the amount of adverse criticism and even condemnation based thereon of those who were called to act in an advisory capacity in the administration of the law, the writer, at the request of the Governor, prepared an official report of that event, some portions of which are necessarily here reproduced.

The execution of William Kemmler, alias John Hart, at Auburn Prison, on August 6, 1890, pursuant to the statute in such case made and provided, marked the first case in the world's history of the infliction of the death penalty by electricity. Since then six other condemned murderers have been legally killed by this method at Sing Sing Prison—namely, James J. Slocum, Harris A. Smiler, Joseph Wood, and Schichiok Jugigo, on July 7, 1891; Martin D. Lippy, on December 7, 1891; and Charles McElvaine, on February 8, 1892; making in all seven cases of successful infliction of the death penalty by electricity in the State of New York.

\* Read before the Section in Public Health of the New York Academy of Medicine, March 16, 1892; also read by title before the Medical Society of the State of New York, February, 1892.

The execution of Kemmler was under the immediate direction and control of the prison warden, the Hon. C. F. Durston, and took place in a room set apart for the purpose, in the basement of the administration building of the Auburn Prison, to which the electric current was conducted by means of an ordinary electric-light wire. The apparatus consisted of a stationary engine, an alternating-current dynamo and exciter, a Cardew volt meter, with extra resistance coil, calibrated for a range of from 30 to 2,000 volts; an ammeter for alternating currents from 0.10 to 3 ampères, a Wheatstone bridge, rheostat, bell signals, and necessary switches; a "death chair," with adjustable head-rest, binding straps, and two adjustable electrodes. The dynamo was an alternating-current dynamo intended to supply 750 incandescent lamps of sixteen-candle power each, and capable of generating, as shown by careful tests made several months prior to the execution, a maximum electro-motive pressure of 2,376 volts, the commercial and mean voltage being 1,680 and 1,512, respectively, the speed of the dynamo being 1,900 revolutions, and of the exciter 2,700. The chair, a square-framed heavy oaken one, with a high, slightly sloping back and broad arms, was fastened to the floor, the feet of the chair being properly insulated. Attached to the back of the chair, above the head-rest, was a sliding arrangement shaped like a figure four (4), the base or horizontal arm of which projected forward, and from which was suspended the head electrode, so as to rest on the vertex, or top of the head, against which it was firmly held by means of a spiral spring. The spinal or body electrode was attached to the lower part of the back of the chair and projected forward horizontally on a level with the hollow of the sacrum. The electrodes each consisted of a bell-shaped rubber cup about four inches in diameter, the part corresponding to the handle of the bell being of wood, through the long axis of which the wire passed into the bell, terminating in a metallic disc about three inches in diameter, and faced with a layer of sponge. The lower electrode was also provided with a sliding arrangement and spiral spring to hold it in place, while a broad strap fastened to the back of the chair and passed around the lower part of the prisoner's abdomen rendered the contact secure. The head was firmly secured by means of conjoined broad leather bands, which encircled the forehead and chin, encasing the eyes and upper portion of the face, and were fastened to the back of the almost perpendicular head rest, while the chest, arms, and legs were secured by broad straps attached to corresponding portions of the chair. The wire attached to the head electrode descended from the ceiling, and that of the lower one passed along the floor to the chair, being protected by a strip of wood.

The dynamo and engine were located in one of the prison shops several hundred feet distant from the execution room; the voltmeter, ammeter, switch-board, etc., were located in a room adjoining the execution room, which contained the death chair, electrodes, and connecting wires. Communication between the meter room and dynamo room was by means of electric signals.

The apparatus used in the subsequent executions at

Sing Sing was substantially a duplicate of that above described, except as regards the location of the measuring instruments, switch-board, etc., and the form and points of application of the electrodes to be hereafter referred to.

Of the twenty-five official witnesses present, fourteen were physicians; two of whom—Dr. E. C. Spitzka and the writer—were officially designated as physicians by the warden, in pursuance of the statute.

Before Kemmler was brought into the room the warden asked the physicians how long the contact should be maintained; the writer replied, Twenty seconds, but subsequently assented to ten seconds, in deference to the opinion of another that a considerably less period of time would suffice—an opinion which doubtless would have been sustained had the electro-motive pressure been sufficiently great.

Unfortunately, in this instance, the voltmeter, ammeter, switch-board, etc., were not located in the execution room; hence none of the official witnesses could know precisely how much the electro-motive pressure and current strength were at the time of making and during the continuance of the first contact. Nor has the voltage or ampèreage in this instance, to the writer's knowledge, ever been officially determined. But reasoning from the known lethal effect of an electro-motive pressure of 1,600 volts and upward, as shown by subsequent executions and by deaths which have occurred from accidental contact with live electric wires, as well as by numerous experiments on animals whose weight exceeded that of man, affords solid ground for the conclusion that no human being could survive the passage through his body of an alternating current of more than 1,500 volts for a period of even twenty seconds, the contact being perfect.

The preliminary arrangements having been completed, Kemmler was brought into the execution room by the warden and introduced to the witnesses, who were seated in a semicircle facing the death chair. On entering the room, the prisoner appeared strikingly calm and collected. In fact, his manner and appearance indicated a state of subdued elation, as if gratified at being the central figure of the occasion, his somewhat limited intellect evidently rendering him unable to fully appreciate the gravity of his situation. He was given a chair near the death chair, and, on being seated, in response to the warden's introduction, said: "Well, I wish every one good luck in this world, and I think I am going to a good place, and the papers has been saying a lot of stuff about me that wasn't true. That's all I have to say." At the warden's bidding, he then arose, removed his coat, and, without the least display of emotion or nervousness, took his seat in the execution chair, calmly submitting to the adjustment of the electrodes and binding straps, himself aiding the proceedings by suggestions and fixing his body and limbs in proper position. Observing the nervousness of the prison officers who were adjusting the straps, he admonished them not to hurry, and to "be sure that everything is all right." He pressed his bared back firmly against the spinal electrode and requested that the head electrode be pressed down more firmly on the top of his head, from which the hair had been imperfectly clipped before he entered the room, remarking, at the same

time, that he desired to perform his part to the best of his ability. The preparations terminated with a final moistening of the electrodes, the whole occupying, at most, between three and four minutes. Everything being seemingly ready, the warden signaled to his assistants in charge of the switches in the adjoining room to turn the lever which closed the circuit and instantly sent the deadly current through the prisoner's body. The instant the contact was made the body was thrown into a state of extreme rigidity, every fiber of the entire muscular system being apparently in a marked condition of tonic spasm. Synchronously with the onset of rigidity, bodily sensation, motion, and consciousness were apparently absolutely suspended, and remained so while electrical contact was maintained. At the end of seventeen seconds Kemmler was pronounced dead, none of the witnesses dissenting, and the warden signaled to have the contact broken, which was immediately done.

For obvious reasons, the only means of determining the question of death while the body was in circuit was by ocular demonstration; so that it can not be positively asserted that the heart's action entirely ceased with the onset of unconsciousness, though most of the medical witnesses present thought that it did.

When the electrical contact was broken the condition of rigidity noted above was instantly succeeded by one of complete muscular relaxation. At the same time superficial discolorations resembling commencing capillary post-mortem changes were observed on the exposed portions of the face. The body remained limp and motionless for approximately half a minute, when there occurred a series of slight spasmodic movements of the chest, accompanied by the expulsion of a small amount of mucus from the mouth. There were no evidences of a return of consciousness or of sensory function; but, in view of the possibility that life was not wholly extinct, beyond resuscitation, and in order to take no risk of such a contingency, the current was ordered to be reapplied, which was done within about two minutes from the time the first contact was broken. The sudden muscular rigidity noted on the first closure of the circuit was again observed and continued until the contact was again broken, when the opposite state of complete muscular relaxation re-occurred. The second closure of the circuit was inadvertently maintained for about seventy seconds, when a small volume of vapor, and subsequently of smoke, was seen to issue from the point of application of the spinal electrode, due, as was subsequently found, to scorching of the edge of the sponge with which the electrode was faced, and from which the moisture had been evaporated by prolonged electrical contact. The odor of the burning sponge was faintly perceptible in the room. There was also some desiccation of the already dead body, immediately underneath the electrodes, especially under the lower one, which will be described in connection with the autopsy.

A careful examination of the body was now made, in which the medical witnesses participated to a greater or less extent. The radial pulse and heart's action had ceased, the pupils were dilated, and the cornea were depressed and flaccid on pressure. In other words, William Kemmler was dead, and the intent and purpose of the law to effect sud-

den and painless death in the execution of criminals had been successfully carried out.

In the excitement and confusion of the moment, occasioned by the belief on the part of some that death was not complete, the second application of the current in Kemmler's case was maintained too long—nearly a minute and a half. If there was a spark of unconscious vitality remaining in the prisoner's body after the first contact was broken—there certainly was no conscious life—it was absolutely extinguished the instant the second and last contact was made. That the man was dead, however, comparatively long before the burning of the sponge and desiccation of tissue occurred, there is no reason to doubt.

The movements referred to were regarded by most of the medical witnesses present, including the writer, as similar in character to those which have occasionally been observed for a short time in animals experimentally killed by electricity, when the contact was too brief or the current strength insufficient, the animal dying, however, in a short time without regaining consciousness—movements which may properly be regarded as involuntary or reflex in character, following the too early interruption of the current, and in no sense a resumption of respiratory function, however much they may appear to be so to superficial observers or to those not familiar with the phenomena referred to, as observed in experiments on lower animals. These movements are very slight in comparison with those usually exhibited by animals suddenly decapitated, and which usually continue a considerable period of time.

Dalton, in his work on Human Physiology,\* refers to observations made by Robin on the reflex action of the spinal cord in the case of a criminal who was executed by decapitation, the head having been severed near the fourth cervical vertebra. Muscular contractions were produced about an hour after execution by scratching with a pointed instrument the skin of the chest at the areola of the nipple while the right arm was lying extended by the side. On irritating the skin at the point and in the manner mentioned there immediately occurred a series of contractions of the pectoralis major, the biceps, probably the brachialis anticus, and lastly the muscles covering the internal condyle, causing the whole arm to approach the trunk, with inward rotation and half flexion of the forearm upon the arm, and bringing the hand toward the chest as far as the epigastrium. On replacing the arm and repeating the irritation as before, a similar defensive movement occurred. This experiment was repeated four times with similar results, except that each time the movement was less extensive; and finally scratching the skin over the chest "produced only contractions in the great pectoral muscles which hardly stirred the limb."

Observations made at executions subsequent to Kemmler's tend to show that reflex excitability of the voluntary muscles disappears much more rapidly after death by electricity than by any other method of sudden dissolution. In the case of McElvaine, executed at Sing Sing on February 8, 1892, Dr. Van Gieson found that reflex action of

the voluntary muscles was absolutely unresponsive—to ordinary mechanical stimuli (see report of autopsy in case of McElvaine)—within two or three minutes after the last contact was broken.

That there were certain defects of a minor character in the arrangement and operation of the apparatus at the first execution by this method will be questioned by no one who witnessed it; but when it is recalled that, notwithstanding these defects, unconsciousness was instantly effected and death was painless—also that less than four minutes elapsed between the making of the first contact and the breaking of the last one, when Kemmler was absolutely dead—it will be conceded by unprejudiced minds that the object to be attained in the infliction of the death penalty, at least so far as relates to the individual—namely, sudden and painless death—was fully realized in Kemmler's case; and had the first contact been maintained for a sufficient length of time, in all probability there would have been no involuntary movement of the body after it was broken, and no unfavorable criticism of the result could then have truthfully been made.

Among other criticisms which appeared in the public press anent the execution of Kemmler was a reported declaration of the most illustrious electrical expert of the age, in which he was made to say that a serious mistake had been committed in not making contact through the hands instead of the head, the skull and hairy scalp being poor conducting media.

However logical this criticism may be from the standpoint of an electrician, it is not sustained by our knowledge of electro-therapeutics and of the physical properties of live bone. In what was intended to be an impersonal reply to this criticism, the writer, in his report to the Governor, took occasion to call attention to certain facts which are well known to physiologists and medical electricians—namely, that the arrest of the heart's action can be as readily effected by destroying or paralyzing the brain center which controls such action as by attacking the heart itself; hence, by including the brain directly in the circuit, the action of the heart would probably be quickly arrested, while at the same time all the vital centers, including that of consciousness, would be paralyzed; also that the brain itself is very susceptible to the influence of electricity, and can be readily affected, sometimes to an alarming extent, by the passage into it through the skull of mild currents, such as are obtained from medical batteries; that the nerve tissues contain an excess of saline moisture, and hence are among the best of conductors, while the amount of organic matter contained in *live* bone is sufficient to render that substance a fairly good conductor. Further, it is not difficult to penetrate the hairy scalp by electricity if the hair be properly moistened, the conductivity of all the tissues of the body being largely dependent on the amount of moisture and salinity contained in them.

In each of the five cases following the Kemmler case \*

\* The head electrode originally suggested in Kemmler's case, but which, for some reason unknown to the writer, was not used, was designed to include the forehead, down to the eyebrows, in the zone of contact.

\* *A Treatise on Human Physiology*, seventh edition, p. 404.

—namely, Slocum, Smiler, Wood, and Jugigo, executed at Sing Sing Prison, July 7, 1891, and Lippy at the same place, December 7, 1891—one electrode was so applied as to cover the forehead and temples, and the other, a larger one, the calf of the right leg, except in the case of Joseph Wood, in which it was applied to the left leg in consequence of the existence of an ulcer on the right one. The calf of the leg was selected because it furnished a broad area of thin skin. The point of contact of the body electrode is not of material importance. It may be applied to the hand, the foot, the calf of the leg, or to any other indifferent part of the body.

The electrodes were thoroughly wet with a solution of salt water before the current was turned on, and were moistened at intervals, when the current was interrupted, with the same solution thrown on them from a syringe.

The following summary of these executions, except as relates to Kemmler, is taken from the official reports made to the warden of the prison, the Hon. W. R. Brown, by Dr. S. B. Ward, of Albany, N. Y., and the writer, who appeared as medical advisers for the State:

The electromotive pressure, as shown by the readings of the voltmeter, taken by Professor L. A. Laudy, of Columbia College, varied from 1,458 to 1,716 volts, while the ammeter showed a variation in current of from 2 to 7 amperes.

The preliminary preparations—that is, from the time the prisoner entered the execution room to the closure of the circuit which rendered him unconscious—occupied, in Kemmler's case, approximately, four minutes; in Slocum's case, three minutes and forty seconds; in Smiler's case, two minutes; in Wood's case, two minutes and forty seconds; in Jugigo's case, two minutes and fifteen seconds; in Lippy's case, two minutes and thirteen seconds; and in McElvaine's case, one minute and forty-nine seconds.

In each instance the prisoner walked deliberately to the chair and quietly submitted to the application of the restraining straps and electrodes without the slightest opposition or show of resistance, and also, save in the cases of Kemmler and McElvaine, without uttering a word in relation to the proceedings. With the single exception referred to (Kemmler's case), there was no exhibition of confusion or excitement on the part of witnesses, nor was there anything unduly repulsive in the executions themselves; on the contrary, everything was done in a quiet, orderly, and dignified manner, in keeping with the solemnity of the occasion. The most striking and constant objective phenomena observed were instantaneous and complete tonic rigidity of the muscular system on closure of the circuit and marked muscular relaxation immediately the contact was broken.

In Kemmler's case there were two contacts, through vertex and lower end of spine, lasting seventeen and seventy seconds, respectively, the last one being unnecessarily prolonged; in Slocum's case, two contacts—twenty-seven and twenty-six seconds; in Smiler's case, four contacts, three of ten seconds each and the fourth nineteen seconds; in Wood's, three contacts of twenty seconds each; in Jugigo's, three contacts of fifteen seconds each; in Lippy's case, four contacts of fifteen, eleven, fifteen and a half, and ten and a

half seconds, respectively. (In all of these five cases contact was through the head and leg.) And in McElvaine's case, two contacts, the first one through the hands\* (immersed to the wrists in liquid electrodes), lasting fifty seconds, and the last one through the head and leg, lasting thirty-six seconds.

In Kemmler's case there were chest movements, and possibly heart-beat, after the first contact (seventeen seconds); in Slocum's, chest movements and radial pulsation after first contact (twenty-seven seconds); in Smiler's, no movement of chest, but radial pulsation after three contacts (ten seconds each); in Wood's, no movement or pulse-beat whatever; in Jugigo's, a slight fluttering of radial pulse when final contact was broken, which rapidly ceased.

In all the cases except Kemmler's and McElvaine's contact was broken for the purpose of wetting the electrodes.

From the foregoing it appears that the time consumed in the preliminary preparations—strapping, adjusting electrodes, etc.—varied from four minutes in the first to less than a minute and a half in the last instance; that the number of contacts varied from two to four, and that the aggregate length of the contacts in each case varied from forty-five to eighty-seven seconds, at the end of which, if not before, in most instances, both conscious and organic life were absolutely extinct.

In other words, the length of time which elapsed from the moment the prisoner entered the execution room until he was absolutely dead was, in Kemmler's case, eight minutes; in Slocum's, six minutes; in Smiler's, four minutes; in Wood's, four minutes and ten seconds; in Jugigo's, three minutes and thirty seconds; in Lippy's, three minutes fifty-three seconds and a half; and in McElvaine's, three minutes and fifty-eight seconds.

It appears, therefore, that the time actually consumed in each of these seven executions, from the moment the prisoner entered the room until he was absolutely dead, varied from eight minutes in the longest to three and a half in the shortest, whereas executions by hanging usually require from fifteen to thirty minutes. In fact, in hanging, it not infrequently happens that the heart continues to beat for that length of time after the fall of the fatal drop. Then, too, far more time is consumed in placing the prisoner on the gallows, pinioning his limbs, putting on the black cap, placing the noose about his neck, and carefully adjusting the knot under his left ear (from whence it sometimes slips at the critical moment, resulting in strangulation instead of a broken neck), than would be required for arranging the preliminary details of an electrical execution. During the preparation of this report the Associated Press dispatches contained an account of a hanging in which the criminal's head was almost completely torn from the body.

\* In view of the opinions expressed by electrical experts of the highest standing, it had been previously agreed that contact should first be made by immersing the hands in two cells, containing tepid salt water, connected respectively with the opposite poles of the dynamo, and, in the event of this not causing cessation of the heart-beat, that recourse should be had to the mode of application through the head and leg employed in the previous executions at Sing Sing Prison. The apparatus was so arranged that either mode of application could be instantly employed at will.

There are abundant reasons for believing that conscious life is destroyed so rapidly by electricity that the application of the current could be repeated several times within the interval that is known to elapse between the receipt of an injury or a peripheral sensory impression, and its conscious perception by the brain through the medium of the sensory nerves. In other words, the electrical current would travel from the point of contact to the brain many times faster than sensory impressions or nerve currents would, the rate of velocity of the latter being, roughly speaking, only about one hundred and fifty-five feet per second—a rate which is quite slow in comparison with the lightning-like velocity of electricity, which travels at the rate of millions of feet per second.

Thus it will readily be seen that an electrical current of lethal energy coming in contact with the body so as to include the brain in the circuit would reach the latter and produce unconsciousness long, comparatively, before any sensory impression, at the point of contact or elsewhere, could be conveyed to and appreciated by that organ, through the process of nerve-conduction, which, as has been shown, requires a distinctly appreciable period of time, the rate of transmission of painful sensations being even slower than that of ordinary tactile impressions.

A striking illustration of the relative slowness of nerve conduction as compared with electricity was shown in a series of experiments in instantaneous photography recently conducted by Professor Muybridge, in the following manner:

The lantern was used to make a series of instantaneous photographs, and in order to make the intervals between the exposures, as well as the periods of exposure, exceedingly short, the plates were exposed and stopped by means of an electric current. One very interesting series of pictures made was intended to illustrate the slowness of the brain in receiving impressions. Two women were employed; one stood in a bathtub and the other sat on a raised chair and poured a bucket of water over the standing woman's head and shoulders. In order to make the shock more intense, Professor Muybridge had filled the bucket with ice-water, unknown to the victim, who would not have awaited the douche so patiently had she known what its temperature was going to be. One view showed the water tipped over and falling, yet not quite touching the girl's head. The next view showed the water splashing from her head and shoulders, and yet there were no signs of sensation. In the third picture she was just beginning to respond to the shock, and the subsequent pictures illustrated the further phases of the response. The point of special interest, however, is in connection with the second view. The electric current had in that case first exposed the plate, and then after a very short interval had shut it off again; that is to say, had acted twice with an interval of time between the two sufficiently long for the sensitive plate to take an impression of the view, and this after the ice-water had touched the woman's shoulders, and before she was conscious of it.

Respecting the resistance offered to the current by the human body, Mr. A. E. Kennelly, of the Edison Laboratory, at Orange, N. J., and who witnessed the execution of Melvaine, in a contribution to the *Electrical Engineer* for February 17, 1892, says:

The electrical pressure at the electrodes was determined from a Cardew voltmeter in circuit with a non-inductive re-

sistance. The current passing through the electrodes was observed from a direct-reading dead-beat ammeter, and the indications of these carefully calibrated instruments afford reliable inferences as to the resistance of a human body, under definite conditions of surface contact, to an alternating current making some 150 periods per second.

From the official records as already published it would appear that in the first application the pressure at electrodes was maintained at approximately 1,600 volts, and the current, which commenced at 2.0 ampères, steadily increased during the fifty seconds of contact up to 3.1, indicating a resistance between electrodes diminishing from the initial value of 800 ohms to a final value of 516, a reduction during the interval of more than thirty-five per cent. The electrodes were metal plates in large wooden receptacles nearly filled with tepid salt water, and in which the hands of the criminal were immersed. Judging from the fact that, although the skin of the hands was blistered over the areas above the water level that had been wetted by first immersion and then withdrawn, yet the skin that remained immersed was entirely uninjured, it seems reasonable to suppose that no very large proportion of the whole resistance of the body would reside in the integuments at the electrodes.

In the second application, forty-three seconds later, the pressure was observed to be maintained at approximately 1,500 volts, and the current which passed between the forehead and the calf of the right leg continued at 7.0 ampères during the thirty-six seconds of contact, indicating a resistance practically steady at 214 ohms during that time. The electrodes were of sponge, kept thoroughly wetted with cool salt water and backed by metallic plates, the area covered by each being about 100 square centimetres. Since no blistering took place immediately below the head electrode, although some blistering occurred at the other, it would appear that no large proportion of the total resistance existed in the contact areas.

The mean activity developed in heat during the first application was thus 4,080 watts, and in the second 10,500 watts, or about 14 E. H. P., this large expenditure of energy accounting for the considerable post-mortem temperatures that are stated to have been observed.

The average resistance of the human body between the hands, immersed to the wrists in dilute solutions of salt or soda, is often overstated in measurement, owing to the vitiating influence of polarization on observations taken with feeble currents in the Wheatstone bridge. Correct readings can, however, be obtained either by bridge measurement to "immediate false zero," or by the use of large resistances inserted directly in the electrode circuit through a galvanometer, so as to employ a higher pressure without pain to the subject, and so reduce the influence of the possible 2.5 volts of polarization counter E. M. F. In either case the mean resistance under these conditions is about 1,000 ohms.

The inference appears to be drawn that the resistance of the body between hands to an alternating pressure of 1,500 volts is only about one half what it is to continuous pressures of 5 volts, or to alternating pressures of 2 or 3 volts, and, from the observations above mentioned, it would seem that the resistance between forehead and calf is very much lower than between immersed hands. While, in conclusion, the general belief is further substantiated that the quantity of current which may pass through the body from a contact with high pressures will entirely depend upon the area and moisture of the contact surfaces, being large with extended and wet surfaces, but, perhaps, comparatively small for brief contacts on dry and limited surfaces of touch.

(To be concluded.)

## ANEURYSM OF THE ASCENDING AORTA

TREATED BY MACEWEN'S NEEDLING METHOD  
FOR INDUCING A WHITE THROMBUS.\*BY ROBERT F. WEIR, M. D., AND  
EMMETT D. PAGE, M. D.

THE good results obtained by Macewen, of Glasgow, in the treatment of internal aneurysms by the induction of what is termed a white thrombus or the deposition in thickened masses of leucocytes on the internal surface of an aneurysmally dilated blood-vessel, led me recently to the trial of this method in a case of aneurysm diagnosticated to be of the ascending aorta. Macewen reported in the *Lancet*, November 22, 1890, three cases of aneurysm—two of the aorta, and one probably of the subclavian artery—wherein a consolidation and cure of the aneurysmal tumor were effected in two instances, and in the third, affecting the ascending aorta, where an autopsy held after the scratching of the inner surface of the aneurysm—for this is the principle of the treatment—had been resorted to some seven times, with several days of rest intervening between the sittings. Macewen not only scratched or irritated in each case with the needle point the interior of the aneurysm, but left the needle impinging on the opposing wall for periods varying from twenty-four to forty-eight hours; this not with the intent of obtaining coagulation on the needle, as in the older methods of treatment, but that the wall of the aneurysm might be more thoroughly roughened. The autopsy of two cases, the second one being a femoral aneurysm similarly treated, showed that the deposition of the white laminated fibrin was greatest where the sac irritation had been most thoroughly applied. Feeling the inutility of any other surgical means, and after submitting the question, in its complete bearings of novelty and want of corroborative experience, to the physician in charge, Dr. C. L. Dana, and to the patient's family, the procedure of Macewen was begun by me June 4, 1891, in a case of thoracic aneurysm, at St. Luke's Hospital, where the patient took a private room, to be more constantly under supervision during the treatment.

The patient was a man of forty-seven years of age, in good physique, of a somewhat excitable temperament, whose symptoms of circulatory disturbance, viz., pain in right arm and side of chest, and pulsations of heart, dated back some six or eight months. Ten weeks previously an attack of influenza occurred during which glycosuria appeared. Four weeks ago the patient noticed a swelling just below the right clavicle with augmentation of the cough and the shoulder pains. When seen first by me, there was a pulsating area over the second and third ribs near the sternum, rising up beyond the skin level fully an inch, with a thick wall. The dullness on percussion extended over a diameter of three inches and a half, stretching upward to the suprasternal notch. No tumor felt behind clavicle in the neck. Heart's action regular. Radial pulsations equal. Urine normal. Considerable pain. Complained sufficiently to require moderate doses of morphine or codeine at night. Slight irregular temperature elevations, supposed to be malarial, and checked by quinine, delayed the first insertion of the needles several days.

The skin over the thoracic pulsating mass having been duly

rendered aseptic, and the proper precautions as to surgical cleanliness of instruments, hands, etc., being resorted to, a slender needle, six inches long and half a millimetre in diameter, was (June 11th) thrust into the most projecting portion of the mass through the chest wall into the aneurysm. It struck the eroded rib at a distance of an inch and a quarter. Its direction then being changed, it was passed into the aneurysm a distance of three inches, and gradually increased to four inches before the resistance showed itself; this opposition was followed by smart coughing with raising of one or two mouthfuls of blood. The lung had been punctured, probably through a thin sac wall, though no resistance had been recognized. The needle was partially withdrawn and endeavored to be carried over another portion of the wall without re-entering through the skin, but it was too slender to permit much change in direction of its point through the firm tegumentary tissues. A second heavier needle, one millimetre in diameter—the first one being left *in situ*—was introduced and the posterior wall decidedly recognized at a depth of four inches and a half, whereupon it was scraped decidedly over a circular area of two inches and a half. The position of this and the first needle was then changed by withdrawing them nearly to the skin level, and then pushing them in in a different direction, so that the posterior wall of the aneurysm was to a fairly satisfactory extent scratched over a space the size of the palm. This surface of the aneurysm was irregular in depth, varying from three inches and a half to five inches and a half from the surface. Left to themselves when touching the posterior wall, only a moderate movement was communicated to the needles by the aneurysmal wall. After the first or the slenderer pin had been in the sac eighty minutes, either scratching the wall or resting against it, it was withdrawn. No more than a drop or two of blood followed. The second pin, the thicker one, was removed after a similar sojourn in the sac for fifty minutes, with the same encouraging result as to the oozing. An antiseptic dressing was applied. The patient had experienced but little pain, and the only untoward symptom was the previously mentioned expectoration of blood, which was not repeated. So far the procedure was tentative to a considerable extent. The size of the needles had not been mentioned by Macewen, and naturally the use of the larger needle suggested the possibility of some hæmorrhage, external or subcutaneous. None such occurred. The thin wall of the sac enforced caution, and it was also recognized that difficulty would be experienced in attacking the lateral aspects of the aneurysm, and it was felt that unless the various punctures made should cause the desired deposit of white fibrin in the bulging anterior, where the most danger to the patient apparently existed, the treatment elsewhere might be of little avail, no matter how satisfactorily it might progress. I did not feel willing, moreover, to leave the needles in place for twenty-four hours or more, as Macewen has done and recommends, since the thinness of the posterior wall had been demonstrated to me.

No reaction followed this first trial.

One week later the needling was repeated, four needles being introduced through the anterior wall—two being used, of a diameter of one millimetre and a fifth, at depths of four inches and a half to five inches, to scrape the posterior wall of the aneurysm, the area reached being at the best a limited one. Two others were carried through the hour-glass opening made up mainly by the eroded ribs in such oblique manner as to reach the lateral aspects of the aneurysm. This, however, could only be accomplished on the median side, and only to a very moderate degree. I was tempted to use a curved needle for this purpose, but the difficulty of managing the point in such a case deterred me from its employment. The extrathoracic portion of the aneurysm was also scratched by the horizontal insertion of a needle, though but little was accomplished by this effort. After the

\* Read before the Section in General Surgery of the New York Academy of Medicine, December 14, 1891.

needling had been continued about an hour, coughing, with expectoration of blood, to the amount of one ounce, with sharp pain, stopped further procedure. The removal of the needles longest *in situ* was followed by spurts of blood, which finger-pressure readily checked. Antiseptic dressings renewed.

Half an hour later the patient complained of severe pain in top of aneurysm and in right arm. This subsided in the course of an hour. No further reaction followed. Temperature and pulse continued normal. Though naturally a very nervous man, his behavior was calm, and he carried out the injunctions of quietness, etc., to the letter.

One week later, but little change was visible in the pulsating mass in the anterior chest wall. If anything, it was more prominent. Thickened, too, from the repeated punctures made in it. Since the last needling he has had, he says, less discomfort and pain than he had previously experienced.

June 18th.—The insertion of the needles was resorted to for the third time. The time occupied in this sitting was an hour and three quarters; four needles used—longest, five inches and a half. The summary of the result was that the posterior aspect of the aneurysm was scratched very satisfactorily over an area of two inches in diameter, at a depth of four inches and a half. Median side of aneurysm also scratched, but only with difficulty, owing to the rib erosion limiting its sweep. Downward—*i. e.*, toward heart—a needle five inches and a half long touched nothing. No pain was felt after the needles had been withdrawn. The patient could feel the scratching readily, and frequently informed me, when in doubt as to whether I had reached the aneurysmal wall, that “he knew I had got there.” Complaint was made more of the needle punctures and of the traction at this point in the various movements of circumduction made, than of the contact of the point of the needle.

He left the hospital three days later, to go to his home in Brooklyn, with the understanding that if no improvement followed in ten to fifteen days the operation should be repeated by one of my colleagues, as I would then be absent on my summer vacation.

The case, I learn subsequently, came under the care of Dr. Atkinson and Dr. Page, of Brooklyn, and from the latter the concluding notes of the history of the case have been sent me.

The patient's subsequent condition did not at all improve. The tumor of the chest-wall enlarged steadily, and increasing pain was experienced, requiring the free use of anodynes.

The surgical treatment was not resumed at the determination of the family.

August 21st.—Rupture of the aneurysm took place internally, causing death in about fifteen minutes afterward.

The autopsy was made by Dr. E. D. Page, assisted by Dr. Hunt and Dr. Belcher, of Brooklyn. Their notes, with the specimen, have been kindly furnished to accompany this report.

They are as follows :

Rigor mortis well marked. Body weight about 155 pounds, usual weight 180.

Tumor ecchymotic somewhat, but smooth externally. It extends from the right axilla, two inches to the left of the median line, and from the clavicle to below the nipple. Circumference at base, externally, twenty inches. Height above chest-wall, three inches. Final remnants of a disorganized blood clot where a thimble-sized tumor existed. This was at the upper and inner place of introduction of the needle. A clot

had disseminated itself outside the ribs over a space of three inches and a half to four inches from pressure of aneurysm beneath it. At this point, too, the wall of the aneurysm was exceedingly thin and ruptured in dissecting the integument from it. Blood had evidently escaped from the aneurysm at the time of the operation into this place, or a vessel of sufficient size to cause the hæmorrhage had been wounded by the needle. No adipose tissue was found between tumor and integument.

The apex of the heart was an inch and a half to the left, and three inches below the left nipple.

The liver, upper margin, was crowded down below the border of the ribs. It was also pushed forward and across the abdominal cavity to left of median line—*i. e.*, the left border of liver. It was also very firm in consistence and very anæmic. Microscopical examination not made.

Diaphragm on right side crowded down to lower rib.

Left lung normal.

Right lung: lobes adherent to each other. Tumor adherent to large portion of anterior part of lung, and so firmly that lung tissue was torn in separating them. This lung was severely encroached upon by the invading aneurysm and caused the increased number of respirations gradually as it increased in dimension. The parietal and visceral pleura were slightly adherent at apex. Otherwise normal.

In the right thoracic cavity was about three pints of clotted blood, pressing the lung upward and the diaphragm downward. This hæmorrhage was the immediate cause of death.

The aneurysm itself was found to be from the anterior part of the ascending aorta and very near the heart. It was filled with a post-mortem blood clot, and nowhere was there to be seen more than a trace of fibrinous deposit. No evidences of the needling were visible. Everywhere the aneurysmal walls seemed thin, especially at upper point already mentioned, and posteriorly where the rupture occurred. In shape it was that of a flattened spheroid, with the antero-posterior diameter the lesser. In size it was six inches and a half by eight inches. The aneurysm, bracing itself against the aorta from which it sprang and also against the elastic lung, did no damage whatsoever to the posterior walls of the thoracic cavity nor to the spinal column itself. Both were in perfect condition, and illustrate the possible ability of these organs to resist successfully long-continued pressure.

Anteriorly the third rib was eroded clear through two inches from the sternum, the latter also being eroded. Second rib badly eroded. The intercostal muscles anterior to the aneurysm had also disappeared by a process of absorption from pressure. The aneurysm, in its relation to the heart, was almost sessile, and, in fact, the specimen herewith presented shows the upper part of the heart dilated, so close is it.

The result of the operation, so far as inducing the formation of a white thrombus is concerned, was, unfortunately, negative. The proximity of the aneurysm to the heart and the consequent interference of the latter's free action, together with the attending dilatation, account for the severe paroxysms of pain following the surgical interference of July 15th.

---

The Microscopical Society of Washington held its eighth annual soirée on Tuesday evening, the 3d inst. The programme embraced an address by the president, Dr. J. Melvin Lamb, on The Field of the Microscope, and the exhibition of fifty-four sets of specimens.

The American Dermatological Association will meet on September 13th at the Pequot House, New London, Conn., instead of at Cushings Island.

## ANÆMIA :

ITS TREATMENT WITH A NEW PREPARATION OF IRON.\*

By REYNOLD W. WILCOX, M. A., M. D.,

PROFESSOR OF CLINICAL MEDICINE IN  
THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL ;  
ASSISTANT VISITING PHYSICIAN TO BELLEVUE HOSPITAL.

WHEN one considers the frequency of pathological conditions of the blood, no apology is necessary for presenting a paper upon this subject. These conditions are found in all grades and classes of people; the pampered daughter of the millionaire is no more exempt than the shop-girl; our foreign-born suffer equally as the native population.

In the discussion of this question I prefer to follow the classification of Oppenheimer and Gräber :

1. Simple anæmia : where both the corpuscles and hæmoglobin are diminished.

2. Chlorosis : where the corpuscles are normal and hæmoglobin diminished (females).

3. Primary chlorosis or pernicious anæmia : where the corpuscles are diminished and the hæmoglobin is relatively increased. Perhaps this might be better stated by saying that the percentage of decrease of corpuscles is greater than that of hæmoglobin, which latter may fall to twenty per cent. The symptomatic varieties of anæmia may be due to many causes :

1. Hæmorrhage.

2. Pathological discharges—*e. g.*, prolonged lactation, sexual excesses, profuse menstruation, suppuration, albuminuria, diabetes, watery diarrhœa.

3. Malignant growths.

4. Toxic and infective processes, such as the fatal cases of pernicious anæmia, reported by Koran, from carbonic-dioxide poisoning, from tea, coffee, tobacco, alcohol, syphilis, tuberculosis, or myxœdema. Here should also be considered those cases of auto-infection designated faecal anæmia by Sir Andrew Clark.

5. Animal parasites.

6. Obstacles to taking food which are mechanical in their nature.

7. Dyspepsia.

8. Venous stasis in cardiac and pulmonary disease.

9. Impaired sanguification in diseases of cytogenic organs, malaria, leucæmia, or Hodgkin's disease.

10. Fever.

*Ætiology.*—Predisposing causes :

1. Sex : female.

2. Age : infancy and youth, old age.

3. Constitution : so-called irritable weakness.

Exciting causes :

1. Deficient supply of food.

2. Want of light and air.

3. Excess or defect of bodily exercise.

4. Unusual states of temperature ; hot or cold temperatures.

5. Increased expenditure of unoxidized material, physiological discharges ; menstruation or lactation.

6. Psychological influences : depressing emotions.

The symptomatology of anæmia may be divided into the general : dropsy, loss of body weight, fever.

Alimentary : retching, vomiting, atonic dyspepsia, constipation, sometimes diarrhœa.

Circulatory : palpitation, faintness, præcordial distress, hiccough.

Respiratory : dyspnœa, slight cough without expectoration.

Integumentary : pallor, hyperidrosis.

Genito-urinary : polyuria, variable menstruation, sexual torpidity.

Nervous : irritable weakness, morbid hyperæsthesia, headaches, tinnitus, neuralgia, convulsions, delirium. In regard to œdema, however, Benezúr and Csatsy found that in the anæmia of Bright's disease the amount of hæmoglobin was not consonant with that of œdema.

The physical signs of anæmia are practically two, so far as the circulatory apparatus is concerned : 1. The *bruit de diable* of Bouillaud, or the *Nonnengeräusch* of Skoda, is due to slackness of the venous wall and a comparative emptiness of the vessels. This murmur is intensified with deep inspiration and arrested by forced expiration or coughing ; it is better heard and is more musical when the patient is standing or sitting than when recumbent. The vibratory sensation, the *frémissement cataire* of Laennec, is due to vibrations of the walls of the veins which are imparted to them by the vibrations of the blood. The muscular contraction produced by turning the head on its axis strengthens the bruit ; so also does light pressure with the stethoscope. The jugular veins can always be compressed by the belly of the omo-hyoid muscle, so that the presence of the murmur must be determined by an avoidance of these conditions. I prefer to accept Hamernyk's theory, that these murmurs are produced by the whirling movement of the blood in the jugular bulb at the lower end of the internal jugular veins, and that these veins have a different-sized lumen along their course and at the termination of the sinus venosus which explains these eddies.

2. The cardiac anæmic murmurs are due to functional disorder of papillary muscles, and are ventriculo-systolic. Balfour believes that these murmurs in the pulmonary area are really due to mitral regurgitation, which in turn is due to defective nutrition of cardiac muscle and dilatation of the ventricular cavity, so that we may say that in the lighter grades of anæmia the murmur in the neck is heard, while as it becomes greater that in the second left intercostal space appears. When this condition becomes extreme we observe intraventricular murmurs, and these are heard at the apex. It is interesting to note that in the following recorded cases as the percentage of hæmoglobin increased the murmur at the apex was the first to disappear, that with further improvement that in the second left intercostal space followed, and that when the percentage approached the normal the *bruit de diable*, last of all, vanished.

The composition of the blood has recently received considerable attention. Gorup-Besanez states that the blood of man contains one part of iron to two hundred and thirty parts of red blood-globules, quoting the analysis of C.

\* Read before the Section in General Medicine of the New York Academy of Medicine, April 19, 1892.

Schmidt. Selmaltz, in his investigations concerning the specific gravity of human blood, found that it varied from 1.059 in the male to 1.056 in the female, the variation being only three one-hundredths. The ingestion of a thousand cubic centimetres of a physiological solution of salt had a very short and feeble influence. The specific gravity may fall to 1.030 in anæmia and cancerous cachexia; it varies according to the amount of hæmoglobin it contains. In serious disease of the stomach the mass of the blood itself is diminished on account of inanition. In phthisis and cardiac disease its density is increased because of the slowing of the peripheral circulation. Jones finds a resemblance between his specific-gravity curves and those of Leichtenstern for hæmoglobin, and explains that the variations of these substances are closely related to those of specific gravity. Hence the determination of the hæmoglobin by means of the color is accurate because it is dependent upon the specific gravity and number of corpuscles.

Meyer and Pernou found that the iron in the liver cells of a fœtus was ten times as great in amount as in a grown animal, showing that it might be stored there to provide for future growth. Jacobi injected iron into the blood-vessels of dogs and rabbits, and found that ten per cent. of it was excreted by the bowels, liver, and kidneys. Of that deposited, fifty per cent. was found in the liver, and the rest in the spleen, the kidneys, the walls of the intestine, and other organs. It was all removed from the blood, however, in two or three hours after its administration. The fact that the excess of iron is stored in the liver may be looked upon as a physiological, not a pathological process.

In estimating the value of a remedy for the increase of the iron in the hæmoglobin, it is necessary that we should not trust entirely to the physical examination of the heart and the blood-vessels and the color of the mucous membranes and of the skin, but also should have an exact means of measuring the hæmoglobin in the blood. Daland has shown conclusively, what I have for some time more than suspected, that the methods of counting blood-corpuscles, such as Gowers's, or the use of the Thomas-Zeiss hæmacytometer, give such variable results from the same specimen of blood, not only when examined by different observers, but also when several portions are examined by the same observer, that the results are by no means satisfactory. Besides, it is extremely trying work for the eyes, and I have for some time abandoned making estimations of the number of blood-corpuscles. In the hæmoglobinometer made by Reichert, of Vienna, which I show, we have not only simplicity of operation, but, I believe, accuracy in ascertaining the amount of hæmoglobin contained in the given specimen of blood.

The technique of this instrument is simple; however, to insure accuracy of results, certain precautions must be taken. In the examination of the blood in the cases that I am narrating to-night the time from 11 A. M. to 1 P. M. was selected. My light was a gas-jet, four-foot burner, five feet distant. I made use of the same capillary tube for all examinations. The finger from which the blood is taken should be cleaned with ether and thoroughly dried.

The cut was made with a sharp-pointed tenotomy knife. The blood should flow freely, and the work should be done quickly, so that clots do not form. The finger must not be squeezed. The capillary tube must be filled at one attempt. Use water for dilution at the temperature of the body, and clean the tube at the time of using. Discharge the blood and water into the cell slowly, so as to avoid bubbles and a marked meniscus at the edge, filling, however, both divisions of the cell to the same level. The water should be discharged with a steady current, so as to thoroughly diffuse the blood into the menstruum. Turn the color-wedge from light to dark and note the reading, then turn it from dark to light and make a second reading, which should correspond with the first. Do not refer to a past record before an examination. Above all things, the examination should be made quickly and neatly. In this method of recording our results we are unbiased by any statement of the patient, and are also independent of any deception in the estimation of the color of the mucous membranes, which readily simulates that of health in those cases, by no means infrequent, where a febrile reaction accompanies anæmia.

In successfully treating anæmia it is necessary to fulfill the *indicatio causalis*, thus presupposing a consideration of the subjects mentioned above. The *indicatio morbi* brings up the consideration of food, which should be nourishing and easily digested, mostly nitrogenous; exercise in the open air, the amount to be regulated; the breaking off of bad habits; and the treatment by remedies.

In recent times it has been observed that the hæmoglobin of the blood has increased after moderate bleeding. Dogiel, on the strength of experiments upon dogs, confirms the deductions of Scholz that moderate bleeding, say with ten or fifteen leeches, does not alter the arterial blood tension, but if it is repeated every three or four weeks the patient gains in weight and the number of blood-corpuscles increases. Vogt and Sehteherbakoff also found the hæmoglobin to be increased under similar circumstances. Schubert treated a number of cases of chlorosis by blood-letting and hot baths. The venesection was at the rate of seven to fifteen grains to the pound of body weight for each bleeding. The patient was kept in bed from twenty-four to forty-eight hours after the operation, and this treatment was repeated once or twice each year. The treatment with laxatives has at times been followed by so much success that Hamilton has said that if he were compelled to treat anæmia by either laxatives or chalybeates he would use the former. In Sir Andrew Clark's theory that anæmia arises in a large number of cases from self-infection—in other words, that a large number of anæmias are of faecal origin—there is certainly some proportion of truth; however, the most rigid and extraordinary antiseptics, which nowadays can be readily obtained by naphthaline, salicylate of bismuth, or beta-naphthol, does not seem to meet with the success that we should expect, although quite recently Pick has professed to have obtained good results in chlorosis from this method. My own personal experience is that it will succeed in only a limited number of cases, so at the present time we can say that neither in bloodletting nor

in laxatives, nor yet in securing intestinal antiseptics, can we hope to obtain such brilliant results as by the administration of iron.

In giving iron we have, up to this time, been hindered by certain apparently insurmountable difficulties. The organic salts of iron have had but a limited use, owing to their comparative inefficiency. The inorganic salts of iron have hitherto presented many disadvantages. Bland's pills, so much lauded and popularized by Niemeyer, certainly fail in a considerable number of cases. Notwithstanding the large amount of iron which one can administer in them, in many instances improvement does not follow their prolonged and uninterrupted administration. I am inclined to think that the potash is partly responsible for this, since it is, as we all know, one of the agents that promote waste. The tincture of the chloride of iron has easily held the first place in popularity and efficiency. Combined with phosphoric acid, when well borne by the stomach, its therapeutics is unassailable. The formula of Flint has been for many years one of my favorites. A coated tongue, feeble digestion, and constipation are supposed to contra-indicate the use of iron. I should rather say that these conditions called for a previous purgation and correction of the digestion, preliminary to a course of ferruginous treatment. On the other hand, I am quite as strongly opposed to the administration of a laxative at the same time with iron, such as is frequently found in its association with aloes, because the metal, being slowly absorbed, requires a slow passage along the intestine. I believe that there is no doubt that large doses of iron are less constipating than small ones, but I do not believe that the final result—namely, the absorption—is so satisfactory. Iron is absorbed more rapidly in catarrhal conditions of the alimentary tract, and in those cases tends to accumulate in the liver. Castellino has found, in his experiments, that hæmoglobin is absorbed rapidly, is always well borne, increases the number of red cells and the specific gravity of the blood, and improves the general condition. If the administration of hæmoglobin, however, is stopped before the normal condition is reached, its effect is only fugitive. In secondary anæmia it fails completely, in that its effects are only transitory. It is more rapid in its action than any other iron preparation. Obviously, the use of this preparation will be extremely limited. The iron found in wines is too small in amount to be considered, yet I am in the habit of prescribing wines, and especially Schreiber's dietetic Tokay, for my patients.

Since, then, we are of the opinion that iron is our sheet-anchor in the treatment of anæmia, and since all preparations hitherto used either have been inefficient or have presented certain disadvantages, we come now to a consideration of a preparation which, I think there is no reasonable doubt, will revolutionize the treatment of anæmia, in that the objections to the strong preparations have been done away with. Dr. George W. Weld, of New York, realizing the great injury done to the teeth by the tincture of the chloride of iron, set about obtaining a preparation which, while retaining all the therapeutic effects, should present none of the disadvantages. After years of experi-

mentation, this preparation has been put on the market by Parke, Davis, & Co., under the name of Weld's syrup of chloride of iron. It was found with the official tincture that the acid would attack the enamel of the teeth, and, curiously enough, in Smith's experiments, when two drachms of the tincture were added to an ounce of water, the destructive energy upon the calcium salts of the teeth was increased, and it was found that, of iron preparations, the chloride was the most harmful, the syrup next, and the wine the least of all. Other preparations of iron, which are bland, are by no means so valuable as the tincture of the chloride of iron. I have tested clinically all the albuminates and peptonates of iron, and all are objectionable because, on the one hand, they are inefficient, frequently requiring administration for many months, and, in the second place, give rise to extremely bad-smelling flatus. If you add water to a simple solution of iron chloride, which is devoid of other acid, you get the basic salts of iron in free hydrochloric acid. Weld has shown that these basic salts of iron are not soluble in strong acids, so that they protect the teeth in the same way that alcohol and syrup do; when, however, water is added, these salts are dissolved, and the acid then attacks the enamel. Thus it is seen that it is the free hydrochloric acid that is so destructive to the teeth. In Weld's iron this excess of acid, which is unnecessary for perfect solution of the iron salt, is removed, and in no way does this impair the therapeutic value of the preparation, because the hydrochloric acid is again added to it from the gastric fluids. It is easily assimilated; better tolerated than the old tincture of the chloride, because it does not produce nausea; gives rise to no disagreeable eructations; and contains no alcohol save that which is found in the tincture, of which half an ounce contains only twenty drops. The constipation which is noticeable on the use of all iron preparations is easily corrected by equal parts of fluid extract of cascara sagrada and glycerin, the proper dose to be determined by experiment.

Each fluidounce of Weld's syrup of the chloride of iron contains forty drops, equaling twenty-four minims, of the tincture of the chloride of iron of the United States Pharmacopœia. It is not pretended that Weld's syrup will not stain the teeth; soft-boiled eggs, salads, etc., will of themselves stain the teeth, but it can be asserted that Weld's syrup will not injure the enamel of the teeth. On using a tooth-brush, the surface is always found intact, even after month-long immersion in this preparation. Weld's syrup of the chloride of iron is simply the tincture of the chloride of iron, United States Pharmacopœia, with the excess of acid neutralized and a certain amount of syrup of gaultheria added to improve the taste. The following cases will illustrate its usefulness:

CASE I. *January 15, 1892.*—H. B. C., United States, aged twenty-four, single, no occupation. Glycosurie fourteen months ago. Under Martineau's treatment sugar disappeared from the urine in three months, and has not returned. Has suffered from polyuria; her daily amount of urine sixty to ninety-five ounces. She complains of dull headache in the afternoon. Suffers backache when walking, has nausea and occasional vomiting, trembling, and pains in limbs. Slight cough without expectoration,

dizziness and fainting spells. Dyspnoea, which is marked on ascending stairs. Her diet has not been restricted.

*Physical Examination.*—Pallor, lips bloodless, not œdematous. Pulse 92, small and weak. Anæmic murmur in right side of neck, also in second left intercostal space. Apex beat weak, otherwise normal. Liver easily felt at edge of ribs. No enlargement of spleen. Urine, ninety-four ounces, free from albumin, sugar, and casts. Specific gravity, 1.018, acid. Reichert's hæmoglobinometer, seventy-eight per cent. Ordered Weld's iron, two drachms three times daily.

*February 13th.*—Reichert's hæmoglobinometer, eighty-five per cent.; quantity of urine, fifty ounces, normal. Anæmic murmur has disappeared from second left intercostal space. Improvement marked as regards symptoms and faintness. Pulse good, 82, and of fair volume. Ordered Weld's iron, three drachms three times daily.

*March 14th.*—Hæmoglobinometer, ninety-one per cent.; much improvement in headache and backache. No nausea or vomiting; cough, however, still continues. Less dyspnoea; pulse 72, of good force; murmurs have both disappeared; liver normal; urine, sixty-two ounces. Ordered two drachms Weld's iron three times daily.

*April 11th.*—Symptoms are entirely relieved. Urine, fifty-five ounces; specific gravity, 1.017; no sugar, albumin, bile, or casts. Liver normal in size. Reichert's hæmoglobinometer, ninety-eight per cent. Discharged cured.

CASE II. *January 19, 1892.*—L. D., aged seventeen, single. Sick one year. Complains of headache, which is frontal, constant, sharp, but not enough to keep awake at night. Sometimes worse in middle of day. Pulse weak. She is languid, disinclined to exertion, sometimes dizzy, but never faints. No cough; formerly palpitation, marked shortness of breath, hands and feet cold. No appetite, no distress after eating. Bowels regular every day. Catamenia anticipate two or three days. Flows four days, not profuse, of good color. No urinary or bowel symptoms.

*Physical Examination.*—Pulse 78, weak, small, and of low tension. Tongue pale and flabby; teeth indent the edges. *Bruit de diable* in right side of neck. Ventriculo-systolic murmur in second left intercostal space. Apex-beat weak, diffused, shortened, somewhat irregular in force and rhythm, on exercise. Reichert's hæmoglobinometer, sixty-six per cent. Ordered Weld's iron, two drachms three times daily.

*February 4th.*—Headache yesterday; is now fourteen days over period. Pulse 72, better. Still has anæmic murmurs. Hæmoglobinometer, seventy-six per cent. Ordered Weld's iron, two drachms three times daily.

*February 23d.*—Has not felt quite so well during last week owing to loss of sleep caused by death of father. Pulse now weaker in force, rhythm is good. Sounds at apex weaker also. Anæmic murmur not so loud as before; heard in neck and at second left intercostal space. Period last week as usual. Reichert's hæmoglobinometer, eighty-four per cent. Ordered Weld's iron, two drachms three times daily.

*28th.*—Has felt very much better since last report. Anæmic murmurs can not now be heard. Reichert's hæmoglobinometer, ninety-three per cent. Ordered Weld's iron, two drachms three times daily.

*March 15th.*—Hæmoglobinometer, ninety-seven per cent.

*April 3d.*—Pulse, 68, good; lips of excellent color. Hæmoglobinometer, one hundred and two per cent. Discharged entirely well.

CASE III. *January 23, 1892.*—M. McC., United States, aged seventeen, sick three weeks. Vomiting constantly, whether stomach is full or empty. Vomits a whitish matter, never bloody. Pain in head in both temples; not always present, but

worse on vomiting. Dizziness on going up stairs, also dyspnoea. Short, dry cough, which is slight; palpitation of heart on walking; appetite fair. Bowels very constipated, no urinary symptoms. Menstruation very irregular for last three months and continues two days without pain; discharge pale and scanty. Sleeps well and is drowsy in day-time. Has pains about neck.

*Physical Examination.*—Tongue clean, pale, and flabby. Conjunctivæ pearly. Lips pale, no swelling of feet. Pulse, 90, feeble, compressible; slight anæmic murmur in right side of neck, also in second left intercostal space. Apex beat weak, with but little impulse. Reichert's hæmoglobinometer, sixty-three per cent. Ordered Weld's iron, half an ounce three times daily.

*February 7th.*—Has felt better, headaches and dizziness better, shortness of breath less marked. Anæmic murmur in second intercostal space has disappeared. Reichert's hæmoglobinometer, seventy-four per cent. Ordered Weld's iron, three drachms three times daily.

*24th.*—Has not taken medicine for two days. Nausea has returned; heart sounds, however, are better. Reichert's hæmoglobinometer, eighty-eight per cent. Ordered Weld's iron, two drachms three times daily.

*March 3d.*—No nausea, no vomiting; dizziness absent; very little shortness of breath; pulse, 72, of good volume and regular; no anæmic murmurs. Hæmoglobinometer, ninety-one per cent. Ordered Weld's iron, one drachm three times daily.

*29th.*—Hæmoglobinometer, ninety-eight per cent. Discharged upon the patient's statement that she feels perfectly well.

CASE IV. *January 24, 1892.*—C. B., aged eighteen, single, sick one year. Menstruation at thirteen, always irregular, recurring every three to eight weeks, lasting five or six days; profuse. For the last six months she has had her periods every fourteen days, lasting from eight to ten days, profuse, but little leucorrhœa. Headaches at times constant, worse in the morning. Dizziness, palpitation of the heart, fainting on one occasion, fainting feelings frequently, shortness of breath on ascending stairs, pain in the stomach almost all the time, poor appetite of late. Pain under the right shoulder. As a rule, food does not distress her. Bowels move every day. Before each menstruation there is an attack of diarrhœa. Loss of flesh and strength.

*Physical Examination.*—Pulse, 88, broad, weak, irregular in force and rhythm. Conjunctivæ jaundiced, pupils fully dilated. Lips pale, tongue clean and pointed. An anæmic murmur in the neck, but none in the second left intercostal space. At the apex there is a shortened first sound, varying in intensity and irregular in rhythm. Reichert's hæmoglobinometer, fifty-six per cent. Ordered Weld's iron, three drachms three times daily.

*February 14th.*—After an interval of sixteen days, she flowed six days, the first three days as usual, the last three there was an improvement. Pain during the first day in the stomach, some headache, but less than formerly. Less pain in stomach, no diarrhœa. Reichert's hæmoglobinometer, seventy-one per cent. Ordered Weld's iron, two drachms three times daily.

*21st.*—Headaches, dizziness, fainting feelings were all improved; appetite good. Reichert's hæmoglobinometer, seventy-nine per cent. Ordered two drachms Weld's iron three times daily.

*March 12th.*—At the last period she flowed for six days; her head aches very little, the dizziness is better, there is no palpitation, and no fainting; no shortness of breath and very little pain in the stomach; food does not distress her; pulse, 72; heart beats stronger than at last report. The murmur in

the neck is less loud. Reichert's hæmoglobinometer, eighty-seven per cent. Ordered Weld's iron, two drachms three times daily.

22d.—No murmur is now heard, and she has greatly improved in appearance and feelings.

April 4th.—No headaches; she has slight dizziness and is restless at night; pulse, 68, good. Reichert's hæmoglobinometer, one hundred and three per cent. Discharged well.

CASE V. January 26, 1892.—E. H., Ireland, aged nineteen, single. Sick five weeks. She was a tea fiend. Vomited after eating, but not at other times. Pain in stomach before vomiting. The matter vomited is food unchanged. Belches wind. Bowels irregular, constipated, move two or three times a week, pain before movement. The head aches in left frontal region, dizziness, shortness of breath on walking, violent palpitation on ascending stairs. Menstruation absent for two months, usually irregular, from five to seven weeks, flows three days, color good, no pain. She has been losing flesh of late and has poor appetite.

*Physical Examination.*—Pulse, 92, weak, compressible, small. Conjunctivæ pearly. Tongue pale, tremulous, flabby. Anæmic murmur in neck, also in second left intercostal space. Apex beat and sounds normal. Reichert's hæmoglobinometer, forty-nine per cent. Ordered Weld's iron, three drachms three times daily.

February 24th.—No vomiting or stomach pain, headache absent, palpitation and dizziness improved. Anæmic murmur in neck, also in second left intercostal space. Reichert's hæmoglobinometer, sixty-five per cent. Ordered Weld's iron, two drachms three times daily.

March 10th.—Has returned to tea-drinking and has some vomiting, otherwise improved. Anæmic murmur in second left intercostal space is now absent. Reichert's hæmoglobinometer, seventy-eight per cent. Ordered Weld's iron, two drachms three times daily. Tea was forbidden.

15th.—Considerable improvement; vomiting has completely disappeared; murmurs now heard only in neck. Hæmoglobinometer, ninety-one per cent. Ordered Weld's iron, two drachms three times daily.

April 12th.—This patient has not yet reported, but, judging from her improvement, she is now well.

CASE VI. February 4, 1892.—L. C., United States, aged eighteen, single. Sick two weeks. Two weeks ago she had cold in chest, cough, expectoration, which was whitish, hard to raise. Dizziness, shortness of breath. In menstruation considerable pain, but nothing else unusual. Headaches on top of head, sometimes fainting feelings. Obligated to sit down suddenly. Bowels very constipated. Poor appetite. Food distresses her; nausea.

*Physical Examination.*—Pulse, 98, small, feeble, slightly irregular. Conjunctivæ pale, pearly. Mucous membranes anæmic. Tongue coated, tremulous, and flabby; anæmic murmur in neck and second left intercostal space and roughened respiration. Reichert's hæmoglobinometer, fifty-two per cent. Ordered Weld's iron, three drachms three times daily.

18th.—Much improved, but is still weak; shortness of breath and headache still present, but not so marked. Cough and expectoration less, appetite much improved; bowels now regular, food does not distress her; pulse, 90, of fair volume, and respiration normal; anæmic murmur in second left intercostal space less marked. Reichert's hæmoglobinometer, seventy per cent. Ordered Weld's iron, three drachms three times daily.

March 15th.—Murmur heard only in neck, and that is not marked; slight cough, dyspnoea absent. Reichert's hæmoglobinometer, eighty-two per cent. Ordered Weld's iron, two drachms three times daily.

April 6th.—Feels perfectly well. Hæmoglobinometer, ninety-five per cent. Iron to be continued in same dosage for two weeks. Discharged from observation.

CASE VII. February 12, 1892.—S. M. F., United States, aged thirteen; sick one year. Complains of headaches, dizziness, languor for several months; fair appetite; sweats easily; coated tongue; constipation, sometimes palpitation. Cold does not result in cough, but tonsils rapidly enlarge. Has not menstruated.

*Physical Examination.*—Pale, skin soft, easily grasped, blue veins showing on forehead. Conjunctivæ pearly; lips pale; mucous membranes the same. Anæmic murmur in neck, also in second left intercostal space. No pulmonary signs; abdomen full. Scapulæ prominent. Expansion half an inch in chest, showing thirty-six inches on expiration; muscles soft. Pulse, 78, weak. Reichert's hæmoglobinometer, eighty-three per cent. Ordered full diet, pulmonary gymnastics, and Weld's iron, one drachm three times daily.

March 7th.—Great improvement in appearance as regards muscles, but still anæmic murmurs are present. Abdomen less protuberant, scapulæ less prominent. Reichert's hæmoglobinometer, eighty-seventy per cent. Ordered Weld's iron, two drachms three times daily.

21st.—Chest expansion, two inches in expiration; its measurement is twenty-nine inches. No murmurs. Checks and lips of good color. Pulse, 72, good. Reichert's hæmoglobinometer, ninety-two per cent. Ordered Weld's iron, two drachms two times daily.

April 10th.—Chest expansion, two inches in expiration; its measurement is twenty-nine inches and a half. Feels very well. Reichert's hæmoglobinometer, ninety-nine per cent. The iron discontinued.

CASE VIII. February 8, 1892.—M. S., France, aged thirty-two; sick one month. Always healthy; for the last month headache in temples constant, sleep interrupted by it. Vomiting of food and mucus for two days; some pain in stomach; poor appetite; bowels regular every day. Of late some dry cough; palpitation on exertion; never dyspnoea. Loss of flesh; no swelling of feet; sometimes fainting feelings.

*Physical Examination.*—Tongue pale and flabby; mucous membranes pale; anæmic murmur in neck, also in second left intercostal space; apex sounds weak; pulse, 90 and weak. Menstruation regular, but scanty and pale. Reichert's hæmoglobinometer, sixty-six per cent. Ordered Weld's iron, two drachms three times daily.

22d.—Less headache and vomiting; palpitation now seldom; no fainting; pulse, 88; heart sounds better, though appetite is still poor; no murmur in second left intercostal space. Reichert's hæmoglobinometer, eighty-five per cent. Ordered Weld's iron, three drachms three times daily.

March 16th.—Her appetite has much improved. Pulse, 72, good. Reichert's hæmoglobinometer, ninety-six per cent. Ordered Weld's iron, two drachms three times daily for two weeks, and then to report if not perfectly well.

CASE IX. February 11, 1892.—E. S., United States, aged nineteen, single; sick six months. Cough not severe, does not keep her awake at night; no vomiting; expectoration whitish, scanty, and easy to raise; generally only in the morning. Palpitation of heart; shortness of breath, however, is absent. She has lost flesh and more strength. Her headaches are constant. She never faints; has cold hands and feet, but no dizziness; appetite good; food does not cause distress; constipation; has no menstrual symptoms, except scanty flow and cramps.

*Physical Examination.*—High-pitched inspiration and expiration at right and left apices; whistling bronchophony; crepitant râles down to upper border of third rib; rest of chest

normal; first and second sounds of heart accentuated; anæmic murmur in neck slight; soft blowing ventriculo-systolic murmur at apex. Pulse, 72, weak, but regular. Lips pale, œdematous, mucous membranes pale. Reichert's hæmoglobinometer, seventy-one per cent. Ordered Weld's iron, three drachms three times daily.

*February 25th.*—Cough improved; expectoration yellowish. No palpitation or shortness of breath. Feet now cold, but not the hands. Has had no menstruation since January 15th. Pulse, 66, of better volume. Lips not so pale. Reichert's hæmoglobinometer, eighty-five per cent. Ordered Weld's iron, two drachms three times daily.

*March 10th.*—Has but little cough and scanty expectoration. No coldness of feet. Has menstruated since last report. Color improved, otherwise no change. No murmurs either in neck or apex. Reichert's hæmoglobinometer, ninety-four per cent. Ordered Weld's iron, two drachms three times daily.

*23d.*—Feels first-rate; has no headaches, no coldness of hands or feet. Pulse, 68, good. Inspiration less high pitched; no whispering bronchophony; no râles. Pulmonic second sound slightly accentuated. Hæmoglobinometer, one hundred and two per cent. Ordered to stop iron; discharged well.

CASE X. *February 11, 1892.*—M. O'B., United States, aged seventeen, single; sick five weeks. Suffered from chorea three years ago, with repetitions each spring. Constant headaches at vertex keep her awake at night. Shortness of breath on exertion; palpitation, which is fluttering, on ascending stairs; also pain about the waist; frequent fainting; dizziness; sometimes ringing in her ears; appetite poor; food distresses after eating; nausea, but no vomiting; bowels regular; cold hands and feet. No disturbance in menstruation, except cramps. The feet swell, also the face

*Physical Examination.*—Lips pale; œdematous. Pulse, 96, weak and irregular. Anæmic murmur in neck, also ventriculo-systolic murmur at second left intercostal space and at apex. Reichert's hæmoglobinometer, fifty-one per cent. Ordered Weld's iron, three drachms three times daily.

*February 25th.*—Slight chorea in left side of the face and in the left arm. Headache better; does not keep awake nights at present. No pain or palpitation of heart; dizziness on two occasions; feet still cold; has not been unwell for five weeks; feet do not swell, neither does the face. Pulse, 84, more regular. Murmurs are still present. Reichert's hæmoglobinometer, seventy-two per cent. Ordered Weld's iron, two drachms three times daily.

*March 17th.*—Menstruation since last report, but not unusual. Shortness of breath improved; no palpitation; appetite good; no distress after eating. Pulse, 72, still weak. Murmur at the apex very faint. Chorea diminished. Reichert's hæmoglobinometer, eighty per cent. Ordered Weld's iron, two drachms three times daily.

*30th.*—Chorea less marked. Murmurs only in the neck. Pulse, 68, better force. Hæmoglobinometer, ninety-one per cent. To continue with Weld's iron for a month.

CASE XI. *February 14, 1892.*—A. C., United States, aged twenty-one, single; sick for four years. Tubercular family history. For the last two years she has been subject to colds. Cough usually not marked, save in the morning; no expectoration; appetite poor; never distressed after eating. She sometimes complains of dizziness and faintness; sometimes dyspnoea and palpitation, especially on exertion. Four years ago she had infiltration of the right apex, which was presumably tubercular.

*Physical Examination.*—Slight dullness over the right apex, and increased transmission of voice sounds, especially the whispered voice; markedly high-pitched and prolonged inspiration;

no râles. Pulse, 92, weak. Pupils dilated; conjunctivæ pearly. Anæmic bruit in neck on right side; no heart murmurs. Reichert's hæmoglobinometer, fifty-three per cent. Ordered Weld's iron, three drachms three times daily.

*March 7th.*—No cough, appetite good, no dizziness, no faintness or shortness of breath, and very little palpitation, save on ascending stairs; no headaches. Her food does not distress her after eating; bowels regular every day. Reichert's hæmoglobinometer, seventy-one per cent. Ordered Weld's iron, two drachms three times daily.

*20th.*—Appetite excellent; feels generally better. Pulse, 68, good. Lips good color, no anæmic bruit in neck, and all pulmonary signs have improved markedly. Reichert's hæmoglobinometer, eighty-eight per cent. Ordered Weld's iron, two drachms three times daily.

*April 10th.*—Has markedly improved. Pulse, 66, good force and volume. Hæmoglobinometer, ninety-nine per cent. Ordered to omit all medication.

CASE XII. *February 16, 1892.*—K. M., United States, aged nineteen, single. Sick three months. Always well until this. Complains of shortness of breath on exertion, palpitation of heart, throbbing in epigastric region, and sometimes coldness of hands and feet; headaches on top of head constant, but worse on being tired; dizziness; sometimes weak and fainting spells. She has no cough or expectoration, no swelling of feet; is regular in menstruation, pain before flow for three days, flow becoming more scanty and pale; appetite good; bowels constipated; no distress after eating.

*Physical Examination.*—Pulse, 102, weak. Skin and conjunctivæ pale. Tongue clean, tremulous, and flabby. Loud anæmic murmur in right side of neck. Rough blowing murmur in second left intercostal space. First sounds of heart weak; tenderness of liver, but no enlargement; spleen normal, no pulmonary signs. Reichert's hæmoglobinometer, forty-six per cent. Ordered Weld's iron, three drachms three times daily.

*March 5th.*—No shortness of breath, palpitation improved, feet still cold; has had one attack of headache which lasted three days; no fainting. Last menstruation was, as usual, of scanty flow with pain. Her appetite has markedly improved; anæmic murmur in neck and second intercostal space still present, although not so loud. Reichert's hæmoglobinometer, sixty-two per cent. Ordered Weld's iron, three drachms three times daily.

*15th.*—Shortness of breath the same, headaches improved, also palpitation. Pulse, 71, good. Reichert's hæmoglobinometer, seventy-four per cent. Ordered Weld's iron, half an ounce three times daily.

*April 2d.*—Has no symptoms excepting occasional headaches. Pulse, 68, good. No murmurs. Reichert's hæmoglobinometer, ninety-eight per cent. Patient discharged well.

In making an analysis of these cases, we may say that the cause of the anæmia in Case I was a state of malnutrition following diabetes and arising in the liver. Cases II, VIII, and XII evidently became anæmic through overwork, loss of fresh air and sunlight. Case IV is accounted for by the menorrhagia from which she suffered, and which was cured during the last week of observation by curetting of the uterus under ether: her improvement, however, dated from the commencement of the treatment by iron. Dyspepsia evidently was the cause of the anæmia in Case III, which could well be named as one of Sir Andrew Clark's fæcal anæmias. I believe that the cure was obtained quite as readily with the administration of iron as it would have been with beta-naphthol, and I speak after considerable ex-

perimentation with intestinal antiseptics. Case X developed her usual spring chorea while under treatment, yet the attack was mild and improved rapidly. Case V was a tea fiend, and a great portion of the result could be justly assigned to the breaking off of the habit. Cases VI, IX, and XI were of the tubercular diathesis, and Case VII should be added here, as the condition was one of hypotrophy, such as has recently been described by Solis-Cohen. Iron, when change of life, scene, and habit can be obtained, is certainly a most valuable prophylactic. In all these cases outdoor exercise was insisted upon, for iron to be of the most value must be sunned, regular hours for sleep and meals and a nitrogenous diet prescribed, and the bowels regulated by cascara sagrada and glycerin.

*Conclusions.*—1. In anæmia iron is by far the best remedy.

2. Of all preparations, the tincture of the chloride is the most valuable.

3. This preparation is objectionable in that it excites nausea, disgust, and vomiting, stains and destroys the teeth.

4. These disadvantages are obviated in Weld's syrup of the chloride of iron.

5. In removing these disadvantages, its therapeutic efficacy is not in any way impaired.

690 MADISON AVENUE, April 12, 1892.

## THE SARATOGA WATERS:

THEIR USES AND ABUSES.\*

BY LEONARD S. RAU, M. D.

In taking up this subject, I do so in order to try to revive an interest in the medicinal use of these waters rather than to hope to be able to say anything new about them; for they have been used and abused for so many years, and there has been so much written about them, that it would be presumptuous on my part to attempt to tell you anything new. After practicing for four summers at one of the principal hotels in Saratoga, I have seen and learned much in regard to these waters, and, as some of my experiences have been interesting and instructive, I make this my plea for reading a paper to you on so old and threadbare a subject.

Let me begin by dividing the principal waters into several general classes: First, the cathartic waters, as represented by the Congress, Hathorn, Empire, Carlsbad, etc. Next the alkaline waters, such as Vichy, Kissingen, and Geyser. Then the iron waters, examples of which are the Columbian and Washington. Besides these may be mentioned the High Rock (the oldest of all), the Excelsior, the Red Spring with its baths, the Favorite, the Patterson, the White Sulphur, the Hamilton, etc. There are some twenty-eight in all, and they contain the various *salts, iodine, iron,* etc. Careful analyses have been made of each, but I shall not trouble you with any of these.

It would seem natural to believe that even a layman could understand that a combination of all, of many, or even of several of these waters, might bring disastrous results,

and yet it has been my privilege to see this very thing done over and over again. Early in the summer of 1890 the Kensington Hotel was visited by a large number of school teachers on their annual excursion. They received invitations to visit the various springs, and, starting out early in the morning, they began to drink the waters, and some of them were not content until they had tasted of all the various kinds, so that when night came I was kept busy going from one patient to another, trying to relieve most violent colicky pains and endeavoring to control severe diarrhœas. Some of the patients told me frankly that they drank anywhere from twenty to twenty-five glasses of water that day. It is useless to add that fruits, corn, salads, pastries, and what not were freely indulged in whenever they found a few moments spare time between their drinks. Seriously speaking, however, some of the cases suffered intensely; several showed marked symptoms of collapse, requiring considerable stimulation, morphine, atropine, etc.; and one case terminated fatally, whether or not as a direct result of drinking the water I am unable to say, for I could not get a complete history of the case. I shall take the liberty of briefly relating as much of the history as I was able to obtain:

Miss B., aged twenty-five, teacher, sent for me on the night of the 8th of July, 1890. She had been perfectly well up to this time. I found that she had been drinking the waters freely, and that toward evening she was seized with vomiting and diarrhœa and severe griping pains. I applied a mustard leaf over the epigastrium and gave a powder of bismuth, opium, and ginger, which was to be repeated hourly until the vomiting and diarrhœa were controlled. She took in all three powders, each containing half a grain of powdered opium. Next morning, though weak, she left Saratoga with the rest of the party for Lake George. A week later I received a letter from New York stating that she had had no vomiting or diarrhœa after she took the third powder, but that twenty-four hours after I had last seen her, while on her way home, she was seized with intense pains in the abdomen. Physicians were summoned. They found her suffering with general peritonitis and she died on the fifth day. This was certainly a very sad termination of an excursion.

Many people, some physicians included, consider the waters worthless and ineffective. My experience just related may perhaps convince them to the contrary. There is and can be no doubt that if the waters are properly used and a regular diet observed—the patients, in other words, living "*Kurgemäss*"—much benefit may be derived from their use. My friend Dr. Burchard, in a paper on this subject written some few years ago, strikes the key-note of the situation by saying: "The trouble is that the people won't eat porridge instead of birds, especially when they have to pay for birds and not for porridge." Another great trouble is that the springs are owned by private individuals, whose principal object, of course, is to make their spring a financial success. The result is that men are continually boring for new springs, and every little while they meet some old spring in their search for a new one, the waters become mixed, and the old and what was believed to be re-

\* Read before the Metropolitan Medical Society, December 9, 1891.

liable spring becomes polluted. Of course, the owner soon finds out the trouble, but he can not afford to close his spring while the damage is being repaired, and consequently the public are the sufferers. This fact was demonstrated in the summer of 1888, when a number of my patients, by only drinking one or two glasses of Hathorn water, were seized with violent cramps and vomiting. Other physicians had similar experiences, and inquiry showed that the water had become mixed with the water from another spring. The damage was, however, quickly repaired. The springs do not seem to be in the same condition every year, so that patients often say to me: "Doctor, why is it that last year one glass of water acted splendidly on me, whereas this year two or even three glasses seem to have little if any effect?" I can only explain this fact by supposing that the waters really do change in character, for a time at least. And now in reference to the question of the springs being doctored. It is, of course, next to impossible to obtain any definite information in regard to this matter. I am willing to believe that the springs at times are charged with carbonic-acid gas, but have no positive evidence to that effect; but I do not believe that salts and other ingredients are added to them.

The fact of the springs changing in character leads me to speak of the recommending of different waters by physicians living at a distance from the springs. Patients before leaving the city go to their physician and say: "Doctor, I am going to Saratoga; what water shall I drink?" and he recommends one in good faith, of course, but in reality knowing nothing about the condition of the water. To illustrate this: I called on a medical friend on my return from the springs one fall, and he asked me which cathartic water I found most satisfactory. I told him the Empire. Next summer all his patients were drinking Empire; but it so happened that this was an off year for Empire, so the result was unsatisfactory for both physician and patients. Many people, too, drink the waters because they are so accessible, and think that on general principles they will do them good, for it would never do to be in Saratoga and not drink the waters. Over and over again, while walking on the piazza or in the corridor of the hotel, I am accosted by an acquaintance, who stops me and asks in an off-hand way (of course, he does not expect to pay for this): "Doctor, what water do you think I had better drink?" or, "Don't you think that Congress is a very good cathartic and would do me good?" As to his physical condition, of course, I know nothing, and yet he wants me to recommend medicine for him. They drink the waters as they please, or as their friends advise them, and then, when they obtain no beneficial results, the natural inference is that the waters are worthless. I assure you, gentlemen, that I am not consulted ten times during a season as to just what waters to drink, how to drink them, and how to live while drinking them; and some of my Saratoga colleagues tell the same story. You all know how different this is in Europe. There every watering-place has its regularly appointed physicians; the people come from all over the world and consult one of these physicians; he lays out a plan of diet and a mode of living, extending over from three to six weeks, and the pa-

tients carry out these rules conscientiously—in fact, they have to; they have no alternative. But how is it in Saratoga? The people go there, seldom if ever consult a physician, immediately begin to drink the waters *ad libitum*—the Congress, the Hathorn, or what not—eat everything on the varied bills of fare, go to the races, indulge in their favorite mixed drinks, gamble till early morning, and then, after a couple of weeks, grow weary, or their funds give out, they leave the place thoroughly disgusted, rather worse than better, and regretting not having gone to Carlsbad instead. Other people really do get up early, drink their water conscientiously, but pay little or no attention to diet. There is no doubt in my mind, and I could cite a number of cases to illustrate this, that, did the people who come to Saratoga to drink the waters, drink them as they would do or have to do abroad, they would obtain just as much benefit therefrom, for there can be no doubt of the cathartic and cholagogue action of the Congress, Hathorn, Empire, etc., or of the antacid and diuretic action of the Vichy, Kissingen, or Geyser. I have obtained most excellent results in cases of constipation, gastro-duodenitis, hepatic engorgement, gastritis, dyspepsia, etc., by recommending a plan of treatment somewhat as follows:

Rise at 7 A. M.; go to the spring (Congress, Carlsbad, Hathorn, or Empire); drink a glass of water *hot*; walk for ten minutes; another glass of water, hot or cold; walk for half an hour to an hour. Breakfast, consisting of milk, eggs, meat, coffee, or tea diluted. Avoid raw fruit, hot rolls, or fresh bread. Then go to stool. At 11 A. M. one to two glasses of Vichy (medium); walk for half an hour or so. Dinner at two. Eat no fried meats or fish, no salads, no corn, no pastry, no raw fruit. Take a rest or a nap till five, then a walk or a drive. At six, one glass of Vichy. Supper at 7:30. Light diet—milk, toast, eggs, stewed fruit. At nine, another glass of Vichy, and retire at ten. This plan to be kept up for not less than three weeks, avoiding all mental excitement. If there is a rheumatic tendency, the Red Spring or magnetic baths three to four times a week, Vichy with meals and Geyser at night, have given me satisfactory results. Diabetics and patients with uric-acid diathesis do extremely well on Vichy or Kissingen in large quantities. In chlorotic and anæmic patients I have been much pleased with the effects of Columbian or Washington (the iron waters), being careful to tell my patients only to drink these waters from one and a half to two hours after eating, for, unless these directions are given, the patients always complain of severe headache after taking the water. These waters just mentioned I have found most satisfactory; but there is no doubt of the efficacy of many of the others, and the paper would be too long were I to attempt to describe the uses of each of the twenty-eight springs.

Unfortunately, the great mass of people who visit these springs annually do so for recreation rather than health, so that the noise, the excitement, the style, gambling, racing, etc., keep away the invalids, who know that in the height of the season they can obtain little rest, for, although they may not care to participate in the festivities, still they feel them to be somewhat contagious, and are not

sure that they can resist the various temptations, and so prefer to stay away. The majority of those drinking the waters do so as a pastime, obtain little, if any, beneficial results, and return to their homes firmly convinced that the waters have lost their efficacy and that Saratoga can no longer be considered a health resort. This view is being rapidly spread over the country, and unless radical means are taken to convince people to the contrary, this resort will soon be a thing of the past, as a watering-place, at least. Let me, for one, raise my voice against these abuses and try to make you gentlemen believe as I do—that the virtues of the Saratoga waters exist now just as they always did, only they are not taken advantage of. No one who knows Saratoga will deny the healthfulness of the place, with its bracing air, dry climate, and magnificent trees. Perhaps I can give no better proof of this than by telling you that at the Kensington Hotel, where many families with a countless number of children of all ages congregate every summer, in the past four summers there has not been a child ill for five consecutive days. I doubt whether any physician can furnish better statistics than that.

Much can be done by physicians to correct this erroneous idea of the lost virtues of Saratoga. Let them, instead of in an off-hand way saying to their patients: "Oh, go to Saratoga for a few weeks, drink the waters and enjoy yourselves," tell them to consult a physician when they get to the springs. Let them give their patients a letter to the physician, stating the nature of their ailments, etc. The owners of the springs should either consolidate into a stock company for mutual benefit and protection, or there should be some State supervision and each spring should have its own physician whom patients can consult if they so desire, and who will see that the spring is in a good condition and that the patients are taking the waters according to their physicians' directions. The hotel managers should have printed bills of fare for people who drink the waters, these to contain no article of food which ought not to be taken while drinking the waters.

By some such means as these much, very much, could be done to change the rapidly developing opinion of the inefficacy of the Saratoga waters, and thousands who now cross the ocean every year to obtain relief could obtain it in their own country without the annoyance of an ocean voyage, foreign travel, and expense, and, furthermore, they would tend to bring back Saratoga, the garden-spot of America, to its former glory and usefulness.

## A MODIFICATION OF WYETH'S METHOD OF BLOODLESS AMPUTATION AT THE HIP JOINT.

BY STEWART LEROY MCCURDY, M. D.

DENNISON, OHIO,  
PROFESSOR OF ORTHOPEDIC AND CLINICAL SURGERY,  
OHIO MEDICAL UNIVERSITY, COLUMBUS, OHIO;  
LECTURER ON TOPOGRAPHICAL ANATOMY AND LANDMARKS,  
WESTERN PENNSYLVANIA MEDICAL COLLEGE, PITTSBURGH, PA.;  
SURGEON, P. C. C. AND ST. L. RY. CO.

THE advance made in amputations at the hip joint, as suggested by Professor John A. Wyeth, must be considered one of the principal ones in modern operative surgery. The operation is described by Wyeth as follows:

The patient being placed in position with the hip of the side to be operated on well over the corner of the table, the foot is elevated, and an Esmarch bandage applied to drive the contained blood toward the heart. The bandage should not be tightly put on over the seat of the disease for fear of driving septic matter into the circulation. With the rubber bandage still in position, the needles are next introduced.

Two steel mattress needles, three sixteenths of an inch in diameter and a foot long, are used. The point of one is inserted an inch and a half below the anterior superior spine of the ilium and slightly to the inner side of this prominence, and is made to traverse the muscles and deep fascia, passing about half way between the great trochanter and the iliac spine, external to the neck of the femur and through the substance of the tensor vaginae femoris, coming out just back of the trochanter. About four inches of the needle should be concealed by the tissues.

The point of the second needle is entered an inch below the level of the crotch, internally to the saphenous opening, and passing through the adductors comes out about an inch and a half in front of the tuber ischii. No vessels are endangered by these needles. The points are protected by corks to prevent injury to the operator's hands.

A piece of strong, white rubber tube, half an inch in diameter and long enough when tightened in position to go five or six times around the thigh, is now wound very tight around and above the fixation needles and tied.

The Esmarch bandage is removed, and five inches below the tourniquet a circular incision is made, and a cuff, which includes the subcutaneous tissues down to the deep fascia, is dissected off to the level of the lesser trochanter, at which level the muscles and vessels are divided squarely and the bone sawed through. All vessels (including the veins) which can be seen are tied with catgut, and the smaller bleeding points can be discovered by slightly loosening the tourniquet, which is then entirely removed.

The remaining portion of the femur is now easily enucleated by dividing the attached muscles close to the bone and opening the capsule as soon as it is reached. . . .

One other important point I wish to emphasize—viz., the advisability in certain cases of doing this operation in two sittings.

In one of my cases the patient was greatly exhausted, and after dividing the femur at the lesser trochanter and securing the vessels, fearing the supervention of shock, as indicated by the pulse, I closed the wound, which healed by first intention. At the first dressing (on the seventeenth day), the remaining portion of the bone was removed by an incision over the trochanter major. The recovery was uninterrupted.

I should prefer to complete the operation at one sitting, but cases will occur where the danger of shock may be obviated by stopping short of enucleation, leaving this for a week or two when reaction and convalescence are assured.

In neither of my cases was there any bleeding, and, in fact, amputation at the hip joint is now a bloodless operation.

I have some hesitation in even presenting a modification of an operation devised by so eminent a surgeon, and one that has been so extensively used by surgeons throughout the country. It has occurred to me, however, that the disadvantage of even having it necessary under extreme circumstances to subject a patient to a second operation should be avoided if possible.

Some have been content with what is known as Jordan's operation, which is performed by making an incision from over the greater trochanter to the end of the stump and down to the bone. The head of the bone is then disarticulated and the soft parts are dissected from the trochanters and shaft down to a line with the lower edge of the flap. The head of the bone thus liberated is swung out so as to admit the assistant's hand into the cavity, pressure being made internally upon the femur with one hand and externally with the other hand. With the assistant still at his task of controlling the vessels, the surgeon proceeds to make the flaps, ligate the femoral, etc.

To perform this operation well, one must have a skillful, trusty, and, above all, muscular assistant. The task of controlling the femoral artery with the fingers while the hip joint is opened and the head and neck of the femur are dissected from the dense soft structures surrounding it, with the making of the flap and the ligating of the vessels, is, to say the least, trying.

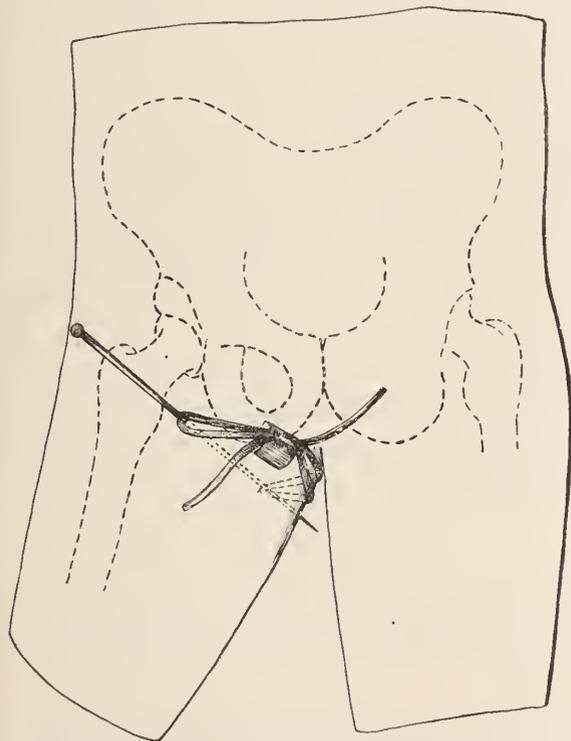

FIG. 1.

An effort has been made to combine what appears to be the advantages of both the above-described methods, and at the same time make the operation as bloodless as Wyeth's and as rapid as Jordan's. As is shown in the accompanying drawing, the Wyeth operation is so modified

as to be performed with but one needle instead of two, and *always at one sitting.*

First draw a line from the most prominent point of the greater trochanter to the perinæum. The needle is entered on this line at a point just internal to the femur, and is passed directly through the thigh so as to make its exit just below the *tuber ischii*. Passed through at this point the needle will be external to all the important blood-vessels, and the only hæmorrhage possible will be from the smaller vessels upon the external aspect of the thigh. A figure of 8 is now made by throwing a round rubber tourniquet around the projecting ends of the needle, over the internal aspect of the thigh, sufficiently tight to destroy femoral pulsation beyond the tourniquet. The flaps are now made, which is followed by disarticulation.

After ligating the blood-vessels, the cord and needle are removed and the stump is ready for final dressing. The point of the needle should be guarded, as Wyeth suggests, with a cork.

The second cut is prepared in view of carrying out the same idea of a bloodless amputation at the shoulder joint.

FIG. 2.

The steps in such an operation are at once suggested to the surgeon, after having studied the rules laid down for the hip operation.

---

**The Death of Dr. Samuel H. Orton**, formerly of New York, took place at South Norwalk, Conn., on April 26th. He was a graduate of Princeton College and of the College of Physicians and Surgeons of the class of 1852. He was prominent as a surgeon in the regular army, during the late war, at Newark, at New Orleans, at Fort Schuyler, and elsewhere. He resigned from the army at the close of the war, and was appointed examining surgeon of recruits at New York, in which office he remained until the spring of 1891. He was in his sixty-third year at the time of his death.

**The Lenox Medical and Surgical Society.**—At the next meeting, on Monday evening, the 9th inst., Dr. Freeman will read a paper on The Dispensary Abuse.

FRANK P. POSTER, M. D.

NEW YORK, SATURDAY, MAY 7, 1892.

PUERPERAL ECLAMPSIA.

This topic formed the subject of a very interesting discussion at a recent meeting of the Berlin Medical Society. The discussion followed a paper by Professor Olshausen, who took a somewhat conservative view of the ætiology and treatment. He favored the self-intoxication theory, but would not commit himself as to the nature of the poison further than to say that it arose from a hindered functional activity of the kidneys. One of the speakers advanced the theory that the pathological factor was pathogenic bacteria, a theory which he said received support from the investigations of certain French bacteriologists of the micro-organisms in the urine of eclamptic patients. Still, he admitted that these investigations lacked reliability. In reference to the embola of fat found in the lung tissue, Virchow stated that they occurred very frequently and in great abundance. The same condition obtained in crushing injuries of bones, in which cases the fat presumably came from the crushed marrow. But that could not be the source of the fat embola in eclampsia, and they did not come from the liver, as was held by some. He maintained that they arose from the adipose tissue—which, he said, gynecologists were in the habit of styling connective tissue—of the pelvis, which was subjected to traumatism by the child's head during an eclamptic seizure. The embola, therefore, must be considered as an effect and not as a cause. In the many autopsies Virchow had made, the kidneys, in the majority of the cases, had shown only slight changes, such as were frequently seen in other conditions in which eclampsia did not occur.

In the matter of treatment, Dürrssen advocated his method of rapid delivery by incising the cervix, and if need be the vagina and perinæum, and extracting the child with the forceps or by turning. He regarded incision of the cervix as quite safe provided the upper part was dilated and the incision made through the lower, or vaginal, portion only. When the upper part of the cervix was not sufficiently dilated, he passed a thin-walled colpeurynter, filled it with air, and forcibly drew it down, thus dilating the internal os, and then he made the incisions into the lower part. The most recent statistics of puerperal eclampsia showed a maternal mortality of fifty per cent., and a foetal mortality of twenty-five per cent. Of twenty-six cases which he had treated in this manner, all the women had been saved and only two of the children had died.

Olshausen, while agreeing with Dürrssen as to the advisability of his method in certain severe cases, considered it too extreme to be applied in every case. Cases did occur in which the obstetrician could foretell, after the first or second seizure, that they would pursue a favorable course and that the uterus would empty itself without any interference. These cases

could be safely managed by the means hitherto employed, and without exposing the patient to the risk of what was, after all, a dangerous procedure. This seems the most reasonable view to take. Still, to our mind, credit must be given to Dürrssen for advocating a method that would have saved many a woman who has been sacrificed by the delay attending the means hitherto employed for evacuating the uterus of its contents.

PENSIONS FOR THE CITY HEALTH DEPARTMENT OFFICERS AND EMPLOYEES.

THE recent mortality among the employees of the health department who were exposed to typhus fever, as well as the past experience of that department in the death of officers and employees exposed to contagious diseases in the discharge of their official duties, has suggested the establishment of a pension fund for the benefit of their heirs, similar in features to the plan of the Police Pension Fund. A bill for this purpose that has been introduced into the Senate provides for the creation of such a fund, to consist of all fees for searches and transcripts of records of births, deaths, and marriages kept in the Bureau of Vital Statistics, all fines and penalties for violations of the sanitary code and health laws, and such sums as may be annually appropriated by the Board of Estimate and Apportionment from the proceeds of theatrical and excise licenses. The bill also provides that the board of health shall be the trustee of this fund, and grant pensions to any physician or employee of the disinfecting corps or of the hospitals for contagious and infectious diseases who, while in the performance of his duty or by reason of its performance, shall have become permanently disabled, either physically or mentally; such pension not to exceed one half or be less than one quarter of the annual compensation of such physician or employee. To a widow or minor children of such physician or employee a pension not to exceed \$300 per annum is to be granted, the pension to lapse if the widow remarries or when the children come of age. The bill further provides that any physician or employee may, after twenty years' continuous service in the department, on his own request or on a physician's certificate of disability, be retired on half pay, the latter not to exceed \$1,200 per annum, and to be continued during the life of the pensioner.

While the last clause in the bill is manifestly just—for the very nature of their occupation is apt to bring on early disability, like that of a soldier, a sailor, a policeman, or a fireman—still, at the present time it seems as if it might jeopardize the success of the remainder of the bill, as creating a new corps of pensioners.

It is unnecessary here to argue that death or disability incurred in the line of such duty is as heroic and as worthy of the proposed recognition by the State as that in the case of the policeman or fireman who strives to protect life and property. Indeed, it is comparable with that of the soldier or sailor who risks his life to protect his country from the invasion of an enemy, only in the present case we have the more insidious enemy, disease.

Any medical officer in the army or navy, engaged in such duty, could feel while discharging it that his widow and children would be cared for in case of his death. We believe that this consideration has nothing to do with the efficiency with which the duty is discharged, as is shown in the case of those officers of the Marine-Hospital Service, whose families are not pensioned, who have died in the discharge of dangerous duty, as well as by the loss of life among medical volunteers during the yellow-fever epidemics of 1873, 1878, and 1879. Still, this fair recognition of the existence of an obligation by the State might make the mental condition of an official engaged in such duty less anxious.

It is to be hoped that the present Legislature will enact this law, and do justice to an efficient class of public servants.

## MINOR PARAGRAPHS.

### A MEDICAL EDITOR ASSAULTED.

DR. JOSEPH H. RAYMOND, editor of the *Brooklyn Medical Journal*, made some editorial comments on the results of a libel suit recently tried in Brooklyn, in the May issue of that journal. These comments were to the effect that the outcome of the trial, which was unfavorable to the plaintiff, was acceptable to the medical profession of Brooklyn, and the editor promised a later and fuller review of the testimony. These comments were the occasion of an attempted assault upon the editor with a whip by Dr. Charles N. Dixon Jones, a son of Dr. Mary Dixon Jones, the plaintiff in the suit. If Dr. Raymond's opinion of the tone and judgment of the medical profession was correct, an assault upon him was the sure way to elevate him into the position of a martyr; if his opinion was incorrect, a horsewhipping was not in any wise likely to alter his mind for the better. There does not seem to be much opportunity for a cowhide in the argument of medical questions. The accounts, as given in the daily papers, indicate that Dr. Raymond was very little, if at all, injured. The notoriety is probably, however, excessively annoying, and can not be lessened, since he has indicated that he must prosecute his assailant.

### THE ALLEGED DISCOVERY OF A MEASLES BACILLUS.

ALLUDING to the alleged discovery by Dr. Canon and Dr. Pielicke, of the Moabit Hospital, Berlin, of a specific bacillus in the blood and various secretions of measles patients, the *Lancet* expresses its hope that the announcement is not another cry of "Wolf," unless it is to be the last one.

### ITEMS, ETC.

**The Michigan State Medical Society** held its twenty-seventh annual meeting at Flint on Thursday and Friday of this week, under the presidency of Dr. George E. Ranney, of Lansing.

**The New York Hospital.**—Dr. Frank Hartley has been appointed a surgeon to the hospital, to succeed Dr. Thomas M. Markoe, who recently resigned after forty years' service.

**Bellevue Hospital Medical College.**—Dr. A. Alexander Smith has been appointed professor of principles and practice of medicine and clinical medicine in place of Dr. E. G. Janeway, resigned. Dr. Hermann M. Biggs has been appointed professor of materia medica and therapeutics, pathological anatomy, and clinical medicine in place of Dr. Smith, and has been nominated attending physician to Bellevue

Hospital in place of Dr. Janeway. Dr. Henry M. Silver has been appointed demonstrator of anatomy in place of Dr. Biggs.

**A Correction.**—In Dr. Sachs's and Dr. Armstrong's article on Morvan's disease, the word "painful" in the sentence before the last on page 486, should be *painless*.

**Changes of Address.**—Dr. H. J. Boldt, to No. 51 West Fifty-second Street; Dr. S. J. Meltzer, to No. 66 East 124th Street.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 17 to April 30, 1892:*

PHILLIPS, JOHN L., Captain and Assistant Surgeon, is granted leave of absence for one month, to take effect on the final adjournment of the board of officers convened by Par. 1, S. O. 32, c. s. Headquarters Department of Missouri.

DE LOFFRE, AUGUSTUS A., Captain and Assistant Surgeon, is granted leave of absence for fourteen days on surgeon's certificate of disability, with authority to enter the Army and Navy General Hospital, Hot Springs, Arkansas, for treatment.

JANEWAY, JOHN H., Major and Surgeon, is relieved from the further operation of so much of special orders as directs him, in addition to his other duties, to perform the duties of post surgeon at Frankford Arsenal, Pennsylvania.

By direction of the Secretary of War, Par. 13, S. O. 74, March 29, 1892, A. G. O., removing the suspension of the orders changing the stations of APPEL, AARON H., Captain, and CABELL, JULIAN M., First Lieutenant and Assistant Surgeon, is revoked.

RAFFERTY, OGDEN, First Lieutenant and Assistant Surgeon, is granted leave of absence for one month, to take effect on or about May 1, 1892.

SNYDER, HENRY D., First Lieutenant and Assistant Surgeon, granted leave of absence for one month and fifteen days, to take effect when his services can be spared by his post commander.

MUNDAY, BENJAMIN, Captain and Assistant Surgeon, is granted an extension of one month to leave of absence granted in S. O. 40, Department of Dakota, March 19, 1892. S. O. 98, A. G. O., April 26, 1892.

### Society Meetings for the Coming Week:

MONDAY, *May 9th*: New York Academy of Medicine (Section in General Surgery); New York Ophthalmological Society (private); New York Medico-historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Lenox Medical and Surgical Society (private); Boston Society for Medical Improvement; Gynecological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

TUESDAY, *May 10th*: Nebraska State Medical Society (first day—Omaha); New York Medical Union (private); Medical Societies of the Counties of Albany (semi-annual), Greene (annual—Cairo), and Rensselaer, N. Y.; Kings County, N. Y., Medical Association; Newark, N. J., and Trenton (private), N. J., Medical Associations; Camden (annual—Camden), Morris (annual), and Sussex (annual) County, N. J., Medical Societies; Norfolk, Mass., District Medical Society (election—Hyde Park); Franklin County, Vt., Medical Association (annual); Baltimore Gynecological and Obstetrical Society.

WEDNESDAY, *May 11th*: Nebraska State Medical Society (second day); New York Surgical Society; New York Pathological Society; Metropolitan Medical Society (private); American Microscopical Society of the City of New York; Medical Society of the County of Albany; Pittsfield, Mass., Medical Association (private); Franklin (annual—Greenfield), Hampshire (annual—Northampton), and Worcester (annual—Worcester), Mass., District Medical Societies; Philadelphia County Medical Society.

THURSDAY, *May 12th*: Indiana State Medical Society (first day—Indianapolis); Nebraska State Medical Society (third day); New York Academy of Medicine (Section in Paediatrics); New York Academy of Medicine (Section in Genito-urinary Surgery); Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; Medical Society of the County of Cayuga, N. Y.; South Boston Mass., Medical Club (private); Pathological Society of Philadelphia.

FRIDAY, *May 13th*: Indiana State Medical Society (second day); Yorkville Medical Association (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties, N. Y.

SATURDAY, *May 14th*: Indiana State Medical Society (third day); Obstetrical Society of Boston (private).

## Proceedings of Societies.

### NEW YORK ACADEMY OF MEDICINE.

SECTION IN GENERAL MEDICINE.

*Meeting of April 19, 1892.*

Dr. A. A. SMITH in the Chair.

**Anæmia; its Treatment with a New Preparation of Iron.**—Dr. REYNOLD W. WILCOX read a paper with this title. (See page 512.)

Dr. GEORGE W. WELD said that the preparation was practically non-alcoholic; the only alcohol in the syrup, so called, was the alcohol contained in ordinary tincture of chloride of iron, each half-ounce containing twenty drops. Regarding the name of syrup of chloride of iron, when one came to taste it, one would discover that it was not a syrup in the sense of the other syrups, which, as everybody knew, were apt to derange the stomach. In regard to its acidity, it was acid in reaction, and necessarily so to hold the basic salt of the iron in solution, for the moment any solution of iron was brought to a neutral point there would be precipitation of the basic salt, which in this case would be the hydrated oxide. The syrup was not acid enough to destroy the enamel of the teeth or to cause nausea or vomiting. Strictly speaking, there were five ingredients in the preparation—iron, saccharine matter, alcohol, oil of gaultheria, and an alkali used to neutralize the free hydrochloric acid. The oil of gaultheria and the hydrochloric acid were present in a very small percentage. Practically, then, there were only three ingredients—the alcohol, the iron, and the syrup. Some six or eight years before, in experimenting with tincture of chloride of iron, the speaker had placed a tooth in the tincture, and, on taking it out, after three hours, been very much surprised that the enamel was not destroyed in the slightest degree, because he had heard a great deal about the injurious effects of this particular preparation. He had thought it very strange, and had concluded there must be some mistake, but, in order to make sure, he had left it in for twenty-four hours, and on taking it out had again found that the enamel was not at all injured. Then his attention was called to an old experiment—that of putting zinc into strong sulphuric acid, when the zinc was not harmed in the least, but the moment water was added there was an immediate and powerful effect of the sulphuric acid. He then added some water to the tincture of chloride of iron and put the tooth into it. The enamel was entirely destroyed. [The speaker showed a number of teeth that had been immersed in solutions of tincture of chloride of iron of various strengths, which strikingly illustrated the destructive action upon the enamel.]

Dr. A. H. ELLIOTT said that his interest in this subject was purely from a chemical standpoint. Some six or seven years before Dr. Weld had got him interested in his endeavors to counteract the injurious action of tincture of chloride of iron upon the teeth, and, in order to get a thoroughly good idea of what he was working upon, he had made an examination of a lot of enamel of teeth, in order to see the kind of material that was being acted upon by tincture of chloride of iron. Then his

attention was called to the fact that acids generally acted very rapidly upon this enamel; in fact, as near as he could remember, one of the first experiments of the kind had been with a five-per-cent. solution of acetic acid—pretty good vinegar. In that case the teeth were attacked to such an extent that about five or six per cent. of the enamel was dissolved by this simple acid. Other acids would destroy enamel as well, the effect varying with the strength, provided, of course, there was no grease or alkali on the teeth to protect them. Then Dr. Weld had called the speaker's attention to the fact that he had concluded that he could add Vichy water to the tincture of chloride of iron, and thus counteract the acidity. Although this had rather amused him as a chemist, nevertheless he had done it, and had found out afterward by making experiments that he could neutralize the free hydrochloric acid in the tincture of chloride of iron by adding bicarbonate of sodium, which Dr. Weld was practically doing by the addition of Vichy water. By adding too much bicarbonate of sodium the point of neutrality would be passed, and the solution would then, of course, become distinctly alkaline. This naturally would not do, as precipitates would be thrown down, and the preparation be made entirely useless. It became necessary, therefore, to add the bicarbonate of sodium very carefully so that only the free hydrochloric acid would be neutralized, but the solution still be acid in reaction, in order to hold the salt of iron in suspension. The difficulty that Dr. Weld had met with in using Vichy water, or, rather, the difficulties, as there were two, had been, first, that he did not know the strength of the tincture of chloride of iron, for, although the druggists said it was made according to the United States Pharmacopœia, we all knew that there were variations in the amount of the free acid. In the second place, he did not know the strength of the Vichy water, so he could never tell just how much Vichy water to add to the tincture of chloride of iron, unless he had the Vichy water analyzed every time. So that this method of counteracting the corrosive action of the tincture of chloride of iron was not always successful, although it could be used in a number of cases, and he did use it in that way. The speaker had then thought that, if one could use the bicarbonate of sodium carefully and find out how much to add to a stipulated amount of tincture of the chloride of iron, the free hydrochloric acid could be neutralized, and yet the preparation still retain its acidity. This saturation point had been found and syrup of gaultheria added. The speaker still had a preparation of tincture of chloride of iron that had been treated by this method several months before, and there was not the slightest evidence of precipitation of any of the ingredients of the solution, whereas preparations of tincture of chloride of iron treated with Vichy water would precipitate if kept for any length of time.

He had obtained from various places in the city a number of samples of tincture of chloride of iron from pharmacists who were reliable. The actual amount of the solid chloride of iron averaged from 8.6 to 14.7 per cent.; so one could imagine what the preparations were. According to the United States Pharmacopœia, tincture of chloride of iron should contain about thirteen per cent. of the dry chloride. The acid over and above that necessary for the solution of the iron in it—for it must be remembered that metallic iron required a certain amount of hydrochloric acid to clear it—averaged from nothing in one to a sample which contained ten per cent. more than was necessary. A sample of syrup of chloride of iron obtained in the open market had been handed to him, and he had found no free acid in it, but more bicarbonate of sodium than appeared to be necessary. This had caused a curious chemical phenomenon to take place in the syrup—namely, the hydrochloric acid had acted on a portion, with the result that sodium chloride had been formed.

But this had resulted in this one preparation of the syrup, something that had been entirely unlooked for, but that added to the efficacy of the syrup, for in this preparation there were the bicarbonate of the sesquioxide of iron and the protochloride of iron—a very curious and happy outcome, from a chemical standpoint.

Dr. J. C. SMITH had used Reichert's hæmoglobinometer for several months at the same time with Gowers's, and was positive that the first-named instrument is not only more accurate in results, but also far easier of manipulation.

Dr. A. S. DANA spoke of a patient who, on March 2d, had been suddenly attacked with a severe chill, followed by very acute pleuritic pain in the left side. At the end of two weeks a purulent collection broke into the bronchial tubes, and large quantities of pus were evacuated. The patient was very much emaciated, and his anæmic condition became extreme, with severe cough, profuse night-sweats, and a very irritable stomach. He was immediately put on the use of tablespoonful doses of syrup of chloride of iron every four hours, and the dose was increased to three tablespoonfuls, with gratifying results. The cough was relieved to a great extent, the anæmic condition was rapidly improving, the stomach took kindly to the iron, and the patient was on the road to rapid recovery. He had been taking during the preceding two weeks an amount averaging seven ounces and a half of the syrup every twenty four hours, without any stomach irritation. The speaker mentioned also the case of a child, three months old, that had pronounced diarrhœa, milk passing through with the stools in an apparently undigested condition. The abdomen was much distended, and there were nausea and vomiting. After using the usual remedies with no apparent effect, the speaker had resorted to Weld's syrup of chloride of iron, giving teaspoonful doses every two hours. The improvement was marked, almost from the beginning, the nausea and vomiting were checked, the tympanites subsided, and the complexion of the child entirely changed for the better. In a number of other cases he had had unusual success with the same syrup.

Dr. C. E. QUIMBY called attention to a preparation of ozone, and said he believed it was now possible to make a permanent solution of ozone in a neutral menstruum.

## Book Notices.

*Diseases of the Urinary Apparatus.* Phlegmasic Affections. By JOHN W. S. GOULEY, M. D., Surgeon to Bellevue Hospital. New York: D. Appleton & Co., 1892. Pp. xiii to 342. [Price, \$1.50.]

MOST of this work having appeared in the *Journal* during the past six months, it will not be necessary to make any extended review of it for our readers. The old students from Bellevue Hospital especially, with the profession in general, will be glad to welcome Dr. Gouley's work upon the diseases of the urinary apparatus. It is not issued as a treatise on genito-urinary diseases at large, but is chiefly concerned with the phlegmasic affections, of which it is a good exposition, and well worth reading.

*The Medical Annual and Practitioners' Index: A Work of Reference for Medical Practitioners, 1892.* Tenth Year. Bristol: John Wright & Co. Pp. lii to 667.

THE yearly editions of this work have become so familiar to the medical profession that a review, properly speaking, would

be a waste of space and time. It is pleasant to note, however, that the editors have a progressive spirit which annually adds new features to the work. The Dictionary of New Remedies has been improved this year by the introduction of the chemistry of the new synthetic drugs and a dose table of the latest medicinal remedies. This part of the work has been in charge of Dr. Percy Wilde, and is thoroughly and concisely treated. For those who have access to few medical journals this book is invaluable in giving the latest views and methods of treatment of diseases, by the leaders of medical thought.

*Bacteriological Diagnosis: Tabular Aids for Use in Practical Work.* By JAMES EISENBERG, Ph. D., M. D., Vienna. Translated and augmented, with the Permission of the Author, from the Second German Edition, by NORVAL H. PIERCE, M. D., Surgeon to the Outdoor Department of Michael Reese Hospital. Philadelphia and London: The F. A. Davis Co., 1892.

THIS volume considers the subject of micro-organisms in three divisions—non-pathogenic bacteria, pathogenic bacteria, and fungi. The first are subdivided into bacteria that liquify gelatin and those that do not, and the second into those that may be cultivated outside the animal body and those that can not. The tabulation that is followed in the case of all micro-organisms insures their description under the headings of place found; form and arrangement; motility; growth on gelatin, agar-agar, potatoes, and blood-serum; temperature for the best growth; rapidity of growth; spore formation; aerobiosis; gas production; gelatin reaction; and color production.

The name of the micro-organism is followed by that of its discoverer and the title of the journal or book in which it was originally described.

In an appendix there is a description of the technique used in the cultivation and staining of bacteria that will be very useful in laboratory work.

There is no book in the English language that gives the information this does so concisely and yet comprehensively; and it needs but to be seen to appreciate that it is the most serviceable work we have for reference and use in the bacteriological laboratory. The translator has performed his work satisfactorily.

*A Practical Manual of Diseases of the Skin.* By GEORGE H. RONÉ, M. D., Professor of Materia Medica, Therapeutics, and Hygiene, and formerly Professor of Dermatology in the College of Physicians and Surgeons, Baltimore. Assisted by J. WILLIAMS LORD, A. B., M. D., Lecturer on Dermatology and Bandaging in the College of Physicians and Surgeons, Baltimore. Philadelphia and London: The F. A. Davis Co., 1892. Pp. viii to 303. [No. 13 in the *Physicians' and Students' Ready-Reference Series.*]

THIS little book was never intended for a systematic treatise. It is a book for the student or the busy practitioner whose time is too limited to allow him to go over the complete systems of dermatology in looking up the diagnosis of an ordinary case. Its descriptions are brief, but clear and intelligible. The chief diagnostic points of the different diseases are made prominent, and the most accepted methods of treating them are laid down without any theorizing. In his list of conditions for epilation by electrolysis the author forgets to mention the one important factor in the case—viz., a patient's willingness to stand the pain. The indiscriminate way in which the needle electrode is recommended to be inserted into the skin may lead some to believe that it is a perfectly painless procedure, but they will find out their error very soon. It requires considerable pride to undergo the pain necessary for this treatment. This, with a few other

such irregularities, almost necessary in a work of its size, constitute all there is in it to criticise. It is a thoroughly commendable little reference book.

*Psycho-Therapeutics*, or Treatment by Hypnotism and Suggestion. By C. LLOYD TUCKER, M. D., Member of the Medico-psychological Association, etc. Third Edition, revised and enlarged. London: Baillière, Tindall, & Cox, 1891. [Price, \$2.]

IN less than three years this work has gone through three editions, an evidence of the interest the profession takes in this subject and of the popularity of the volume.

The present book is larger than its predecessors, as the author has incorporated such criticisms and reports as have been published since the appearance of the last edition, with a view of throwing all the light possible on the theory of psychotherapeutics.

While there is a strong sentiment throughout the book regarding the value of hypnotism as a therapeutical agent, yet it is urged that the same discrimination should be exercised in its application as in that of any other remedial agent; and the frank acknowledgment of personal failures, as well as the reference to those reported by others, shows the fairness and impartiality with which the subject is considered.

The volume is commended to any one desiring a satisfactory work on hypnotism.

*Les tumeurs de la vessie.* Par J. ALBARRAN, Chef de clinique des maladies des voies urinaires à la Faculté de médecine de Paris (hôpital Necker). 75 figures et 9 planches. Paris: G. Steinheil, 1892. [Prix, 18 francs.]

PROFESSOR GUYON prefaces this work with a reference to the fact that tumors of the bladder have virtually been scientifically studied only during the past fifteen years, and remarks that the accumulation of material, the discoveries in pathology, and especially the advent of cystoscopy, have made a new history of the subject desirable. The fact that the author was his associate for four consecutive years is a sufficient guarantee of the character of the material that he has had access to.

The history of the subject is divided into the ancient, up to 1874, when Billroth proposed the hypogastric incision for the removal of vesical neoplasms; and the modern, subsequent to that date. After considering the structure and development of the normal mucous membrane of the bladder, the subject of classification is presented. Tumors are divided into primary, or those originating in the bladder, and secondary, or those developing by propagation from contiguous structures or by generalization.

The primary tumors are subdivided into those of the epithelial, those of the connective, and those of the muscular tissue, following Bard's theory of cellular specificity.

The tumors originating from the epithelium are subdivided into an atavie group, of an allantoidian type, in which the epithelial cells resemble those of the intestine of allantoidian origin and the epithelium of the villosities of the chorion; a vesical adult group that is subdivided into a variety having a common epithelial layer, one having an epithelial layer in which the polygonal cells have a large nucleus surrounded by clear protoplasm, and one of a glandular type; and epithelioma, including the lobulated or tubulated, cylindroma, carcinoid and reticulated growths, and myo-epithelioma.

Tumors originating from the connective tissue are divided into an atavie group, including sarcoma, myxoma, and fibromyxoma; and an adult group, fibroma. As an adjunct to the connective-tissue tumors, we have angioma.

The muscular tissue tumors include the myomata, while the

heterotopic tumors embrace dermoid cysts, dermoid or horny epithelioma, chondroma, and rhabdomyoma. As an adjunct to this group there is the hydatid cyst.

The pathological anatomy is clearly described and the text is illustrated by colored woodcuts. The ætiology, pathogeny, and symptomatology are well described.

The cystoscopes of Nitze and Leiter, the megaloscope of Boisseau du Rocher, the urethro-cystoscope of Grünfeld, and the panelectroscope are described, and their advantages and disadvantages properly portrayed. The chapter on diagnosis is very comprehensive. Under the head of treatment the various operations for opening the bladder are mentioned, the question of suture is considered, and sections are devoted to resection and total extirpation of the bladder. There is a table of two hundred and twenty collected cases.

The volume is well printed, and, besides the illustrations in the text, there are nine large phototypes of cystic tumors. The work is a valuable contribution to the literature of an important subject.

## Reports on the Progress of Medicine.

### GENERAL SURGERY.

By MATTHIAS L. FOSTER, M. D.

**What is a "Felon"?**—Burrell (*Bost. Med. and Surg. Jour.*, Feb. 4, 1892) is convinced that the term "felon" is very loosely applied to a variety of inflammatory diseases of the finger, and suggests that this term should be abolished and an anatomical classification of the inflammatory affections of the finger be adopted. The classification he proposes is: 1, dermatitis; 2, paronychia; 3, cellulitis of the finger; 4, suppurative thecitis; 5, periosteitis or osteitis of the phalanges. While he feels sure that most practitioners distinguish these various affections, he maintains that the distinction is frequently not made in name, and that the common text-books on surgery neglect to clinically distinguish them. The treatment of these various conditions differs. Dermatitis requires local applications; paronychia, an incision through the nail or its removal, with a proper dressing afterward; cellulitis, a limited incision into the pulp of the finger with evacuation of the pus; suppurative thecitis, an incision through the sheath of the tendon, evacuation of the pus, antiseptics, and immobilization of the fingers, hand, and arm; periosteitis or osteitis, an incision down through the periosteum at the earliest moment. These affections run into one another, and it is at times impossible to make a clear distinction between them, but the distinction is needed, for an incision down to the periosteum is worse than useless in dermatitis, and not necessary in any except in periosteitis or osteitis where such an incision is imperatively demanded.

**Symmetrical Congenital Defects in the Anterior Pillars of the Fauces.**—Toeplitz reports (*Arch. of Otol.*, January, 1892) the observation of two symmetrical openings in the palato-glossal arches of a young man, the right one being slightly larger and somewhat more remote from the margin of the anterior pillar. The margins of the openings were smooth, without a trace of cicatrization. They were elliptical in form, about half an inch long by three sixteenths of an inch wide, and led from the cavity of the mouth into the space usually occupied by the tonsils, which in this case were absent. More marked on the right side than on the left, a quarter of an inch below the margin of the opening, was a slight indication of what might be considered a radiated scar, but to the observer it rather resembled radiated folds. Dr. Toeplitz states that he has been able to find very few similar cases recorded in the literature of the subject.

**Acute Orchitis following Influenza.**—The latest addition to the multitudinous sequelæ attributed to influenza is made by Harris (*Lancet*, Jan. 2, 1892) in the form of acute orchitis. The patient, aged sixty-seven, came under treatment complaining of "pains all over," especially in the back, head, and back of eyes, slight cough, temperature 103.2°

pulse 120, tongue slightly furred, bowels open. Five days later he complained of pain, tenderness, heat, swelling, and redness of the left testicle. This occurred during an epidemic of influenza. The patient had not left his bed and had no trouble with his urine, and there appeared to be nothing to account for the inflammation of the testicle except the theory that it was a sequela to that disease. Briscoe (*ibid.*, Jan. 23, 1892) reports a similar case.

**Intussusception.**—Barker (*Lancet*, Jan. 9, 1892) suggests the following procedure in cases of intussusception which can not be reached from below, and which are found, on opening the abdomen, to be so tightly strangulated that reduction, even if feasible, could end only in disaster, instead of forming an artificial anus or resecting the whole mass of damaged bowel directly and suturing the divided ends together:

"At the point at which the intussusciens receives the intussusceptum the two portions of the bowel are at once united by a continuous circular suture of fine silk taking up the serous and muscular coats of each, and carried on to the mesentery. A longitudinal incision is then made for about two inches through all the coats of the intussusciens on its free margin. This gives access to the sausage-like intussusceptum within. The latter is then drawn out through this incision and is cut across close to its upper end; or, if too long to be first drawn out, it may be cut across *in situ*. A few stout silk sutures are, however, passed through all the walls of the stump as the mass is gradually cut off, and are tied tightly so as to keep the serous surfaces in contact and control all bleeding from the vessels entering it at its mesenteric attachment. The stump is now cleansed, dried, and dusted with iodoform, and is allowed to drop back through the incision into the lumen of the intussusciens. Then the longitudinal incision in the latter is closed by a continuous suture from end to end. Toilet of the surrounding parts and closure of the abdominal wound complete the operation."

Mr. Barker has performed this operation twice, each time on a patient in a desperate condition, and in neither case did the operation avert a fatal result. Nevertheless, he professes to have demonstrated that the operation is quite feasible, that it can be performed in a reasonable time and without much difficulty, and that he is impressed with the feeling that, under less unfavorable conditions and with an increased experience of details, this method will prove very successful.

**Anthrax successfully treated by Excision of the Pustule.**—Lowe (*Lancet*, Jan. 23, 1892) reports two cases in which excision of the focus of inoculation arrested the progress of anthrax. In one the pustule was situated on the neck, in the other on the cheek. It seems strange that such an operation should check the disease, but one fact is established—viz.: that theoretical considerations should never deter any one from operating, not only during the early stages, but at whatever period of the disease the cases present themselves.

**Suprapubic Dislocation of the Head of the Femur.**—Nash reports (*ibid.*) a very unusual and remarkable form of dislocation of the head of the femur which differed very materially from the ordinary pubic dislocation, in which the head of the bone lies on the pubic bone or beneath the anterior-inferior spine of the ilium.

A boy, eleven years of age, was running behind and pushing a swinging boat when he slipped under it. On its return the boat struck his right knee, dislocating the hip. On admission to the hospital there was a contusion over the front of the right knee. The right leg was everted, abducted, and shortened to the extent of two inches and a half or three inches. The head of the bone could be seen and felt lying half way between the umbilicus and Poupart's ligament. Both trochanters could easily be felt on rotating the limb. There was considerable effusion into the soft tissues around the joint. The femoral artery could be felt pulsating on the inner side of the small trochanter. Methylene was given and reduction attempted by means of pulleys and manipulation, but the head of the bone could not by any means be brought below the pelvic brim. The patient was then put into bed with an extension applied; an attack of acute rheumatism supervened, so that over two months elapsed before an operation could be performed. Then methylene was given and an incision was made down to the neck of the femur, the head was exposed, and all the ligamentous and muscular attachments to the neck and great trochanter divided. The tip of the great trochanter was found to be separated and a large amount of periosteum stripped off the back of the femur. Connecting the shaft with

the acetabulum was a mass of bone formed by the periosteum which had been stripped off. The head of the bone was resected, as traction still failed to effect reduction. Six months later the hip was quite stiff and there was about two inches of shortening present.

Mr. Nash states that he has not been able to find any record of a similar dislocation.

**Echinococcus of the Orbit.**—Olga A. Mashkovtzeva (*Med. Obozrenie; Brit. Med. Jour.*, January 23, 1892) relates the case of a pale and very emaciated Tartar girl, two years of age, who was brought to her on account of eye disease of three months' standing. The affection had been steadily growing worse, the child becoming ever more restless, fretful, and sleepless. There was very marked exophthalmia of the right eye, with swelling of the eyelids, œdema, and congestion of the ocular conjunctiva; the globe was dislocated forward and inward, was immovably fixed, atrophied, and degenerated; and the cornea was represented solely by a grayish spot of the size of a lentil. The whole external portion of the orbit was filled with an immovable tumor, homogeneous in its consistence, and indistinctly fluctuating. A malignant neoplasm, growing from either the eyeball or the optic nerve, was suspected and the eye was extirpated. The child bore the operation well, and her general condition rapidly improved. The tumor was found to be an echinococcus cyst of the size of a small hen's egg, containing hooklets, but no secondary cysts, and occupying the site of the external rectus, the lacrimal gland, and the adjacent cellular tissue, all of which were entirely absent. The hydatid was surrounded by a dense fibrous capsule. The whole eyeball was transformed into an equally dense pigmented mass.

**Pneumonotomy and Pneumonectomy.**—Willard (*Univ. Med. Mag.*, February, 1892) has been conducting some experiments on dogs regarding these operations, which he reports, together with a digest of the literature on the subject, and presents the following conclusions:

His experiments in thoracotomy and in bronchotomy show that the entrance of air into the pleural cavity is a far more serious matter as regards the collapse of the lung and of the patient when the lung tissue is normal than when it is diseased or already crippled.

Incision into the substance of the lung with removal of a portion is well borne in dogs. Hemorrhage, though free, is not fatal, and can be arrested by packing.

Adhesion of the parietal and visceral layers can readily be obtained by sutures, and the resulting pleurisy is slight.

Surgically, these experiments point out that similar adhesive inflammation can be secured and thus permit safe incision into tubercular or other diseased lung tissue without infection of the pleural cavity.

A lung can be drawn into the wound made by excision of the ribs and so sutured to the edges of the opening that the pleural cavity can be excluded.

Pneumonectomy, performed for gangrene or for abscess of the lung, offers better results than is possible in cases not treated surgically.

**Abscess of the Brain from Aural Disease.**—Körner (*Arch. f. Ohrenheilkunde; Ctrbl. f. Chir.*, 1892, No. 3) arrives at the following conclusions, after a consideration of the reports of a hundred cases of intracranial abscess due to aural disease, nine operations, and ninety-one autopsies:

1. Abscess of the cerebrum was found in sixty-two cases, of the cerebellum in thirty-two, in both at the same time in six. Children under ten years of age seldom suffer from cerebellar abscess, on account of the great distance of the posterior fossa of the skull from the auditory meatus. Men are about twice as liable to abscess of the brain as women. The right side is affected more frequently than the left.

2. Regarding the extension of the disease from the temporal bone to the brain, he concludes that, contrary to the generally received opinion, in a very large portion of the abscesses of the brain which result from suppurative otitis and develop near the seat of the primary lesion a demonstrable continuity with the same can be found. Therefore, in order to avoid later trouble after an apparently brilliant result, besides emptying the abscess, the diseased bone should be sought and removed.

3. Abscesses of the brain dependent on disease of the petrous bone lie in the immediately neighboring portions of the brain, in the temporal lobe, or in the half of the cerebellum on the same side. In seven of the hundred cases this seemed to be contradicted, and Körner acknowledges

it to be not proved, for to prove it it would be necessary to have data regarding each case, showing that a disease of the temporal bone was present, which could cause abscess of the brain, that no pyæmia was present, and excluding any general tuberculosis or suppurative inflammation of the air passages.

4. The information in regard to incapsulation and quality of the pus was deficient. In one case the odorless condition of an abscess which resulted from a fetid otitis was mentioned.

5. As complications, thrombosis of the venous sinus was found seventeen times on the right side, five times on the left; in the ninety-one autopsies, suppurative meningitis was found seventeen times, rupture into the lateral ventricle ten times, into the fourth ventricle once. The frequency of the complications does not permit the conclusion that these abscesses were inoperable in their early stages.

6. In regard to the diagnosis between otitic abscesses in the temporal lobe and the cerebellum these points must be borne in mind: 1, The age: cerebral abscesses are three times as frequent as cerebellar in children under ten; 2, the seat of the primary bone lesion; 3, labyrinth disease does not certainly indicate cerebellar abscess; 4, location of painful area by percussion; 5, pain, vertigo, and optic neuritis are uncertain signs; 6, disturbances of speech occur only in cerebral affections, but are seldom met with on account of the preponderance of right-sided abscesses.

**Surgical Treatment of the Gall-bladder.**—Ignatow (*Chirurgischeskii Vestnik; Ctrbl. f. Chir.*, 1892, No. 9), after an extensive consideration of this subject, draws the following conclusions:

Operative interference is always indicated by intense pain associated with symptoms more or less plain of closure of the ductus cysticus or choledochus.

Cholecystotomy must be considered the typical operation, because it has the greatest range of application.

The so-called normal cholecystotomy is attended with the least mortality.

In all obscure cases, where the walls of the gall-bladder have undergone more or less marked pathological changes, especially in cholecystitis ulcerosa and empyema of the gall-bladder, normal cholecystotomy is indicated as the least dangerous operation.

Cholecystectomy can not be recognized as a radical treatment for gall stone, and is, therefore, to be confined to cases of malignant disease of the walls of the gall-bladder, and cases of impassable stricture of the ductus cysticus.

The so-called ideal cholecystotomy is indicated in recent cases with only slight changes in the walls of the gall-bladder.

Cholecystenterostomy is the only applicable operation, and in many cases, in the absence of malignant growths, a radical one, for the cure of unremovable stricture of the ductus choledochus.

**Intestinal Occlusion.**—Pernice (*Riforma med.; Deutsche med. Zeitung*, Jan. 25, 1892) has conducted a series of experiments on dogs, in which he completely occluded the intestinal canal at various points. The following is a partial *résumé* of his results:

Death resulted from stenosis of the duodenum in from four to six days, and from stenosis of the ileum in about ten days.

The only positive diagnosis that can be made with regard to locality is between stenosis of the large and of the small intestine.

The symptoms of stenosis of the small intestine are about the same as those of stenosis of the pylorus, but they become less marked the greater the distance of the obstruction from the stomach. These symptoms are dejection, aversion to food, thirst, vomiting, which occurred from half an hour to two hours after ingestion into the stomach, and sometimes without this, particularly of bile, and especially severe in stenosis of the duodenum, rapid and weak pulse, subnormal temperature, emaciation, constipation, and lessened excretion of urine, rarely anuria. In the urine, indican was always present, sometimes bile pigment was found, rarely traces of albumin, once signs of spermatorrhœa. The changes in the blood consisted of a considerable increase of the red and white blood-corpuscles with increase of hæmoglobin during the first few days, and then a gradual decrease until death.

In stenosis of the lower colon, constipation and tenesmus were constant, rarely associated with vomiting. The animals remained lively and took nourishment. Their weight diminished but slightly, there

were no changes in pulse or temperature, while in the blood only an increase in the white and a slight decrease in the red blood-corpuscles was observed.

After death the principal anatomical changes found were emaciation, dryness of the tissues, enlargement of the alimentary canal above the obstruction with atrophy of the part below, great hyperæmia of the liver, and thrombosis of the veins, also hæmorrhages by diapedesis, a thickened condition of the circumportal connective tissue, atrophy of the liver cells, formation of pigment, sometimes biliary engorgement, fatty degeneration of the cells, and atrophy of the acini.

## Miscellany.

**The Physiology and Pathology of the Mammalian Heart.**—In the *Proceedings of the Royal Society*, No. 306, Dr. C. S. Roy and Mr. J. G. Adami, of the University of Cambridge, give the following abstract of a communication of theirs:

Our communication begins by stating that we have sought to study the action of the mammalian heart in conditions (unexcised and intact) as nearly approaching the normal as we were able to make compatible with the employment of exact methods of research. This is followed by a general consideration of the difficulties attendant upon such a study, and of the means by which these difficulties may be overcome.

Under the heading of Methods we describe a *cardiometer* which we employed to measure the contraction volume and the "output," as well as the changes in the volume of the heart other than those due to its rhythmic contractions and expansions. A description is also given of the method of employing it, together with a statement as to the degree of the accuracy with which, according to our experience, the instrument supplies information regarding the changes in the volume of the heart. We then describe an automatic counter, which we employed for measuring out and recording the output of the heart, as obtained by the cardiometer.

This is followed by a description of our *myocardiograph*, which we made use of to record the contractions and expansions of any part or parts of the ventricular and auricular walls without interfering with the movements of the heart. In most cases we employed this instrument to obtain simultaneous records of the contractions of one auricle and one ventricle. We state also our doubts as to the value of observations made on the heart by "button" cardiographs.

Section III begins by a consideration of the relationship between the circumference of a hollow spherical muscle and its cubic contents, this being illustrated by a diagram, and by one or two concrete examples with regard to the bearing of this subject upon the physiology of the ventricles.

We then state the relation between the internal circumference of a hollow spherical muscle and the resistance to contraction of its walls. Reference is also made to the elastic resistance which the heart wall itself offers to contraction, and the bearing of this upon the production of negative pressure within its cavity under certain conditions.

We then consider briefly the effect on the ventricular contractions of changes in the blood pressure within the systemic and pulmonary arteries, pointing out how much the heart has in common with the voluntary muscles of the body, and explaining why the amount of residual blood is liable to changes, concluding with a few remarks upon "failure of the heart."

In Section IV we enter upon a study of the effects of the vagus nerve upon the heart. We begin with the changes in the contraction volume, and point out that, at first sight, our curves seem to show that, other things being equal, the volume of blood expelled at each systole varies in inverse ratio to the rapidity of heart beat. We show, however, that this general law does not hold good for vagus slowing (if, indeed, it be exact for slowing of any kind), which is found to be accompanied by a lowering of the output; that, with moderate slowing, this diminution of the output may be as much as thirty or thirty-five per cent.

We then speak of the increase in the amount of residual blood in the heart which is produced by vagus excitation, showing that this does not necessarily indicate any weakening of the ventricular contractions.

We next analyze myocardiographic records of the action of the vagus upon the heart, showing that the auricular contractions are weakened or arrested, and noting that the influence of the vagus upon the force of the auricular contractions bears no constant proportion to the vagus slowing. By strong vagus excitation or by muscarin the auricles may be completely arrested, it may be, for hours. This complete arrest is, in some cases, led up to by progressive weakening, but sometimes arrest occurs immediately after fairly strong beats, or with fairly strong beats presenting themselves at times during the arrest. These latter cases may be explained by weakening of the excitations which reach the auricles from the sinus, although they are possibly due to diminished excitability of the auricles.

On coming to the effect of the vagi upon the ventricles we find that the distention of the heart during vagus actions is due to the ventricles being more expanded, both in diastole and in systole. We point out that the increased volume of the heart at the end of systole is a necessary result of the increased contraction volume, and combat the conclusions of those who ascribe it to weakening of the ventricular contractions, pointing out that the greatly increased contraction volume increases to a corresponding extent the work done at each contraction. We give detailed reasons for concluding that this suffices to explain the apparent diminution of the ventricular contractions.

We then examine the influence of the vagus upon the tonus of the relaxed ventricles, and point out that the great distention during vagus action is due entirely to increased intraventricular pressure during diastole, and not, as has been asserted by some, to any change in the elasticity of the relaxed ventricular wall.

Next, we consider the cause of the rise of venous (systemic and pulmonary) pressure, and find that this is due not to any increase in the amount of blood entering the veins in a given time or to contraction of their walls, but that it is to be ascribed to the diminished inflow into the ventricles.

The cause of this diminished inflow into the ventricles leading to corresponding diminution of the output is twofold—namely, weakening or arrest of the auricles, and, secondly, the elastic resistance of the ventricular wall to distention. We show that this explanation must apply to both sides of the heart, and that observed facts correspond with it.

We then consider the after-effects of vagus excitation, and show that the temporary increase in the output which is sometimes present may be explained by a temporary increase in the force of the auricular contractions, and by the venous pressure taking some little time to fall after the vagus excitation has ceased.

After this, we examine the influence of the vagus upon the heart rhythm, and show that, when the vagus excitation reaches a certain degree (varying in different animals), the ventricles begin to beat independently of the sinus and auricles; that this rhythm, which is at first slow and irregular, gradually becomes fairly rapid and almost completely regular.

This rhythm, we show, must be looked upon as the same as that which, as Woodridge and Tigerstedt observed, makes its appearance when the ventricles are severed from the auricles. We point out, however, that the independent ventricular rhythm of vagus action is characterized by the slowness with which it establishes itself.

This characteristic is due to the lowering of the excitability of the ventricles produced by vagus action, and we adduce a considerable number of facts showing that the vagus *does* lower the excitability of the ventricles, and that, by means of muscarin and by discontinuous stimulation of the vagus, it is possible to isolate the influence of the vagus on the rhythm and force of the auricles from its influence upon the excitability of the ventricles. The power of the vagus to stop the ventricles temporarily can only be explained by this diminution of their excitability.

We show that, with a certain degree of vagus excitation, irregularity of the ventricles necessarily results, in consequence of the sinus and the ideo-ventricular rhythms interfering with one another; that

this is the common cause of irregularity; and that irregularity may also be caused by the auricles not responding to all the impulses which reach them from the sinus.

We explain that, in rare instances, direct excitation of the vagus may so lower the excitability of the ventricle that the contractions may not extend over the whole of their walls, and may in this way produce the apparent weakening which is sometimes met with.

In Section V we pass on to study the effect of direct excitation of the *nervi augmentores (accelerantes)* upon the heart, and show that the acceleration of the rhythm may be extremely slight if the heart be beating fast, and that the acceleration and augmentation of force of the heart bear no constant proportion to one another. The augmentor nerves increase the diastolic expansion of the auricles and also increase their systolic contraction; but these two effects do not go hand in hand.

Excitation of the augmentors increases the output of the heart, owing to the increased force and frequency of the auricular contractions, the result of this being that the pressures in the systemic and pulmonary arteries rise, while the systemic and pulmonary venous pressures fall. If there be but little quickening, the contraction volume of the ventricles is increased.

The augmentors, on direct stimulation, cause a slight increase in the diastolic expansion of the ventricles, which is passive in nature and due to the increased force of the auricular contraction. The force of the ventricular contractions is increased; they contract more completely, diminishing the amount of residual blood, in spite of the fact that the arterial pressure is usually somewhat raised.

There are certain nerve fibers other than the *nervi augmentores* proper which pass from the stellate ganglion to the heart, sometimes by the annulus of Vieussens to the inferior cervical ganglion, but sometimes as separate branches passing directly to the heart from the ganglion stellatum or the annulus. On peripheral excitation of the cut nerves there is marked weakening of the contractions, both of the auricles and of the ventricles, usually with some degree of slowing, this being sometimes followed on cessation of the excitation by a very well marked increase in the force and frequency of the auricular and ventricular contractions. They may be vaso-constrictors for the coronary vessels, although we give no proof of this.

There are nerve fibers which descend to the heart by the vago-sympathetics, which, on excitation under certain conditions, increase the force and frequency of beat of the auricles and ventricles, and which may be vaso-dilators for the coronary vessels.

Reflex excitation of the vagus produces results which are the same as those of direct excitation of the nerve, and the curves are more typical and satisfactory than those obtained on direct excitation of the nerve.

Excitation of a mixed nerve like the sciatic usually produces effects on the heart similar in kind to those due to direct excitation of the augmentors, but the phenomena are complicated by the greater rise of the pressure in the systemic arteries. Sometimes the increase in force of the ventricle more than counterbalances this increased resistance to contraction, and the amount of residual blood in the left ventricle is reduced; in other cases the increase in force of the ventricular contractions is not sufficient to counterbalance the increased resistance, and the residual blood in the left ventricle is increased.

In Section IX we show that excitation of the central end of a mixed nerve like the sciatic or splanchnic usually affects both the augmentor and vagus centers in the medulla, and that, in nearly all cases, the augmentor center is the more strongly excited of the two, so that augmentor effects show themselves during the excitation, but are succeeded by vagus action on ceasing to excite the nerve. In many cases augmentor effects alone show themselves. When excited reflexly the augmentor center ceases to act earlier than the vagus; the opposite, therefore, to what takes place with direct excitation. In rare cases the excitation of the vagus center may be stronger than that of the augmentor from the first. Although, in the absence of any augmentor action, the vagus does not reduce the force of the ventricular systole, it does unmistakably have the power of inhibiting the strengthening influence which the augmentors exert upon the ventricular contractions.

In Section X, upon the part played by the vagus in the economy, we

show that vagus excitation relieves the heart of work, and therefore of waste, to as great an extent as is compatible with a continuation of the circulation, and conclude that the vagus acts as a protective nerve to the heart, reducing the work thrown upon that organ when from fatigue or other cause such relief is required by it. The presence of fibers in the sciatic and other mixed nerves which cause reflex excitation of the vagus would seem to indicate that this nerve may be used by other parts of the body to diminish the output of the heart and lower the blood-pressure, thereby reducing the activity of the circulation as a whole. The influence of the blood-pressure in the systemic arteries on the degree of vagus activity and the readiness with which the vagus center is called into play by raising the intercranial pressure indicate that the vagus mechanism is specially employed in lowering the circulation so as to limit cerebral congestion. The vagus acts chiefly in the interests of the heart and central nervous system.

The power of the vagus over the heart is limited, and the ideo-ventricular mechanism, which comes into play when the vagus action exceeds a certain limit, must be looked upon as the means by which arrest of the circulation and death is prevented, whenever from any cause the nerve exerts a maximum influence. The power of the vagus to lower the excitability of the ventricles makes their temporary arrest possible, but this reduction of the excitability of the ventricles can not be kept up, no matter how strong the stimuli applied to the nerve, for a period long enough to endanger the economy.

In Section XI we show that the function of the augmentor in the economy is to increase the work and tissue waste of the heart as part of the mechanism by which the nervous system governs the circulation, and that the augmentor mechanism sacrifices the heart in order to increase the output of the organ and enable the ventricles to pump out their contents against a heightened arterial pressure. Such excessive action of the heart is limited by the vagus, which, as we have seen, readily steps in so soon as the call for an increased supply of blood has ceased. It may do so earlier, presumably because the increased blood-pressure or the fatigue of the heart calls for vagus intervention.

In Section XII we consider the mode of interaction of the vagi and augmentores; we point out that when the vagi are paralyzed by section or atropine the augmentores have no control over the cardiac rhythm, and that therefore they can only act by inhibiting the influence of the vagi on the rhythmic center of the heart. When neither nerve is acting on the auricles they contract with a certain force, which is increased by the augmentores and diminished or inhibited by the vagi. The force of the ventricular contractions is increased by augmentor action: this increase can be inhibited by vagus excitation, which latter has otherwise no power to reduce the strength of ventricular contractions.

The force of the heart's contractions is influenced by other factors than the vagi, augmentores, and other nerves. The pressure of the blood in the coronary arteries is one of the most important of these factors. If this be lowered, the contractions of both auricles and ventricles diminish in strength, while a rise of pressure in the systemic arteries causes an increase in the force of the heart's contractions, so that the force of the heart's contractions is to a certain extent regulated automatically by changes in the blood-pressure in the aorta, which is one of the variable quantities affecting the work of the left ventricle.

Change of the volume of blood in the body affects greatly the contraction volume and output of the heart. Injections into the veins of a volume of defibrinated blood equal to one tenth of the total blood in the body may double the output. It is important to note here that there is no increase in the strength of the ventricular contractions; increase in the work, therefore, of the ventricles due to increase in the output has no tendency to automatically increase the force of the ventricular contractions, as is the case with rise of pressure in the systemic arteries. We refer to the bearing of this in cases of plethora.

Increase of the watery constituents of the blood increases the contraction volume and output to the same extent (though only temporarily) as does transfusion of blood, but acts more unfavorably on the heart, seeing that the work done by the ventricles is increased, while the nutritive value of the blood supplied to the coronaries is diminished.

The increased output of the heart both in plethora and in hydræmia is due to rise of pressure in the systemic veins increasing the volume

of blood which enters the right ventricle during diastole. We refer to the bearing of these facts upon the treatment of chlorosis and heart disease.

In Section XIV we consider the limits of the power of the heart to perform the work thrown upon it, and show that in strictly physiological conditions, and in spite of the beautiful mechanism by which the force of the ventricular contraction is regulated, the heart, like the voluntary muscles of the body, is liable to fatigue when the work thrown upon it greatly exceeds that required to maintain the circulation under ordinary circumstances. We take as example the increased work thrown upon the organ during active muscular exertion, and show that exertion and endurance of fatigue are limited mainly by the limited power of the heart to continue supplying the increased amount of blood which is required by the acting voluntary muscles. We show that those luxuries which are forbidden or limited in "training," and which are known to hinder prolonged exertion—such as water, alcohol, tobacco, caffeine—all directly weaken the force of the heart's contractions, and, in the case of water, place the organ under a disadvantage; also that fatigue of the heart leads to dilatation of the organ.

On comparing the power of fatigued ventricles to carry on increased work, as compared with well-nourished unfatigued ventricles, it is found that not only is the strengthening effect of the augmentor nerves upon the individual contractions less in the former case, but also that the fatigued and therefore dilated heart is *per se* unfavorably placed for meeting increase in the work thrown upon it. An explanation is given of the reason why in heart disease failure takes place during exertion.

The part played by the vagus in protecting the diseased heart from harmful overwork is referred to, and it is shown that irregularity of the heart in disease may be explained by the mode in which this nerve, when acting powerfully, releases the ventricles from the control of the rhythmic center in the sinus. The chief forms of rhythmic and arrhythmic irregularity are considered, and it is shown that these correspond with the forms of irregularity which can be produced by vagus action. The irregular heart expends more energy, and its tissues therefore are more wasted, for a given amount of work than the heart which is beating regularly.

The effect upon the heart of imperfect aeration of the blood is, first of all, to produce powerful vagus action from the medullary center; this is usually, though not always, accompanied in curarized animals by diminution of the output of the heart. But reasons are given for assuming that the output would be increased in uncurarized animals, owing to the high venous pressure which results from struggling. Besides the vagus action, it can be shown that asphyxia causes progressive weakening both of the auricles and of the ventricles, and attention is drawn to the fact that the considerable rise of pressure in the systemic arteries in asphyxia is accompanied by vagus effects upon the heart, and not by augmentor action, as is the case, so far as we know, in all other instances in which the vaso-constrictor center is excited in the normal individual.

It is noted that the change in the heart and circulation which takes place during asphyxia points to the conclusion that, when the total amount of oxygen in the blood is lowered, it is for the benefit of the economy that those organs, such as the central nervous system, whose continuous blood supply is a vital necessity, should be richly furnished with blood by constriction of the vessels of the spleen, kidney, and digestive system, whose blood supply can be cut off temporarily without danger to life, and also that the heart should carry on the circulation in a manner involving as little waste as possible of its own substance. This, as we have seen, is the function of the vagus nerve to bring about.

**Epidemic Neuroparesis** is the name given by Dr. B. W. Richardson, of London (*Aselepiad*, ix, 33), to influenza. In all essentials, he says, the symptoms start from a catarrh, and are attended, as might be expected from their rapidity, with more or less of febrile disturbance. They are, in brief, symptoms of a *neuroparesis*, with pyrexia.

From the first the symptoms are nervous in character. The pain, the heaviness of spirit, the languor, are all characteristic of organic nervous shock. The local symptoms in the pulmonary organs are of the same type. The dullness preceding crepitation; the irregular extension

of the pulmonary lesions, in patches, over the lung; the invasion of both lungs at different points; and, in some instances, the sudden congestion of the structure of both pulmonary organs—these signs all point to nervous failure as distinct from acute sthenic pneumonia, as we commonly understand that affection. The character of the expectoration also is special. The well-known rusty expectoration of ordinary pneumonia is not presented in distinctive manner, nor does the urine follow the same changes in relation to the chlorides. There is also another condition which markedly distinguishes the pneumonic paresis from the specific sthenic inflammatory pneumonia—I mean the quickness of the changes, not only from bad to worse, but from bad to recovery. I was called to a patient late one night in consequence of the danger arising from a sudden and extreme congestion of both lungs, from their bases to a point three inches above the apex of each scapula. The resistance to the circulation was extreme, and under the resistance the febrile excitement was considerable, while, from the imperfect aeration of the blood, the cerebral oxidation was vehemently disturbed. It seemed as if death were inevitable, and so it would have been if the commanding influence had continued to exert its sway; a few hours, in fact, would have been sufficient to bring life to an end. It was like a process of rapid destruction of respiratory function. But twenty-four hours later all the general symptoms were relieved in the fullest degree, and the respiratory murmur was so clear that, if my own ear had not heard the difference, I fear I should have distrusted the evidence that might have been brought before me in regard to the modification that took place in so short a period. This was a rather extreme case, and I doubt not that during the late widespread epidemic multitudes like it in the way of rapid intensity of symptoms and comparative rapidity of relief—leaps into and out of danger from pulmonary lesion—have been observed. But this is not the feature of ordinary sthenic pneumonia. It is the feature of a sudden paresis from some temporary nervous shock and nervous failure.

There has been another peculiarity in this epidemic relating to the bronchial complication and the bronchial discharge. There has usually been some excess of bronchial secretion in advanced stages of the affection, but not of secretion of the same tenacious character, and in the same excess, as in common broncho-pneumonia. Hydrops bronchialis has not, in my observation, been a prevailing cause of death, neither has it been, except actually *in articulo*, a troublesome symptom. The term "simple acute bronchitis" could not be applied readily to the cases of most marked character coming under the epidemic; and, when bronchial symptoms have appeared, it has been surprising to see with what rapidity they have disappeared as the influence at the root of the mischief has passed away.

The symptoms in sequence, what some have called the secondary symptoms, have borne out remarkably the idea of the nervous origin of the disease. The cerebral attacks are either dependent on the pulmonary disturbance, or are due to the same influence, interfering with the nervous governance of the cerebral circulation, as that which interferes with the pulmonary circulation. But the cerebral lesion is more continuous, as is common to cerebral and nervous injury; hence the often prolonged stretch of nervous symptoms which follows a fairly quick recovery from the acute stage of the disease. At one time I thought that possibly there was formed in the blood, under the perverted oxidation that is in progress, a new substance of toxic character; and this, indeed, may be the fact. The carbon of the blood can not be naturally oxidized, and therefore the nervous oxidation in the great centers will be perverted. This will, of necessity, lead to disturbed cerebral function, to delirium, to water pressure, and to the coma which is so often a prominent symptom of the later stages in fatal seizures. This central nervous failure would lead in its turn to the congestion of other vital organs, like the liver and kidneys, that are under nervous control, and depend on nervous supply for their natural activity. Thus the mischief of the neuroparesis, commencing in the pulmonary circuit, extends to the whole system; and in observing the symptoms we are practically watching development of phenomena, precisely as when we are watching the development of anæsthetic symptoms under the administration, by inhalation, of a narcotic vapor or gas, like nitrous oxide, ether or chloroform. And the perfection of our art should be to place the patient under such conditions that the influence causing the symptoms shall be

neutralized, and the body be so circumstanced that the natural acts shall swing round into their usual course.

**A Case exemplifying Gross Negligence.**—Mr. Lorenzo D. Bulette, of the Philadelphia bar, contributes the following article to the April number of the *International Medical Magazine*:

It may be of interest to the physician to know that the act of leaving his horse standing unfastened, or if unfastened then unattended, in a populous place, while making a professional visit, constitutes gross negligence, for which he will be responsible to the person who suffers injury thereby; and this too in face of the fact that the known qualities and habits of the animal are such as to induce the belief of perfect safety in so doing. Evidence of the quiet and gentle character of the animal, or to the effect that he was accustomed to stand without being tied, must, in such case, be disregarded by the jury in reaching their verdict.

This is the law as it was laid down in *Overington vs. Dunn*,\* which was an action for damages for an injury caused in the following manner, as appears from the evidence at the trial:

The defendant was a practicing physician, who, on the day the injury occurred, had left his horse and gig in a lane about ten yards from the door of the house in which his patient was. He did not secure his horse in the ordinary way, or leave any person in charge of it. The position of the defendant, while attending his patient, was such that he could see the horse from the place where he stood. But, while the defendant was engaged in the examination of his patient, the horse, unperceived, passed out of the lane into the street leading down through the built-up portion of the city, and, while going at a considerable rate of speed, came in contact with the horse of the plaintiff, which was in a team attached to a wagon. The shaft of the defendant's gig entered the plaintiff's horse, causing an injury from which the animal died.

The defendant's evidence showed, and it was received in this instance without objection, that the horse was well broken, that he was kind and tractable, and that he was accustomed to stand for hours together without being tied. Further evidence, on the part of the defendant, gave a description of the place in which he left his horse. The house was in the suburbs, and built upon a lane or court about thirty feet wide. Across the lane where it opened into the street there was a large gate, which the defendant found open and left it so. Owing to obstructions, he was unable to drive quite up to the door of the house, but he drove as near to it as the circumstances of the place would allow. It also appeared that, owing to these obstructions, it was impossible for the horse to get from the place at which he was left without backing for quite a distance.

The judge before whom the cause was tried charged the jury that negligence was a question of fact for their consideration, but that, in deciding it, they ought not to take into view the peculiar qualities of the defendant's horse; they should rather consider and decide whether the care taken by the defendant would be sufficient in the case of any horse, whatever his known character and disposition. And this, on appeal, was affirmed to be the law.

Negligence is the omission to exercise that degree of care which the law requires; and it can occur only in cases where there is legal obligation to observe care. If no care be taken where the law requires it, the negligence is gross. If some care be taken, but less than the law requires, the negligence is greater or less according to the degree of deviation from the legal requirement.

It is sometimes supposed that, where little or no danger is to be apprehended from the omission of care, the obligation to exercise care is proportionally less or does not exist at all; and such appears to be the view of the defendant in this case. But his idea confounds the fact of negligence with the danger or risk attending it. They are, however, entirely distinct. Cause and effect are not more so. A grossly negligent act, as the law would term it, may, in fact, be attended with very slight risk, while, on the other hand, an act perfectly proper, and performed with extraordinary care, may, from causes not foreseen and for which the agent may not be responsible, be followed by disastrous results.

\* 1 Miles, 39.

In this case there was no evidence of any care used by the defendant to restrain his horse at the time he left him. On the contrary, it is express that he left his horse at large. In the eye of the law his negligence was gross; it could not be greater. He, no doubt, thought that there was no risk attending his neglect. It may be conceded that most persons, as his counsel asserted, would have done as the defendant did, but the event proved that it was unsafe. It was an error of judgment; and the law makes him responsible for the consequences.

**The New York Academy of Medicine.**—The programme for the meeting of Thursday evening, the 5th inst., included a paper on The Reaction of Ether with Urine, by Dr. Andrew H. Smith, and one entitled Practical Hints on the Examination of Urine, by Dr. R. A. Witthaus.

At the next meeting of the Section in General Surgery, on Monday evening, the 9th inst., Dr. W. B. Coley will read a paper on Hydrocele in the Female, with a Report of Fourteen Cases, and Dr. John Ridlon will read one on Fracture of the Neck of the Femur; a Report of Twelve Cases treated by the Thomas Hip Splint.

At the next meeting of the Section in Genito-urinary Surgery, on Thursday evening, the 12th inst., Dr. R. W. Taylor will report A Peculiar Case of Urinary Fever, Dr. Charles Heitzman will read a paper on Pus in the Urine—how to discover its Source, and Dr. Samuel Alexander will read one on Blood in the Urine—how to discover its Source.

At the next meeting of the Section in Pædiatrics, on Thursday evening, the 12th inst., there will be a discussion on Summer Diarrhœa in Children.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. Walter Wyman, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for April 29th:

CITIES.	Week ending—	Population, U. S. Census of 1890.	Total deaths from all causes.	DEATHS FROM—										
				Phthisis pulmonalis.	Yellow fever.	Small-pox.	Varicellæ.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.

**Some of the Dangers of washing out the Stomach.**—The April number of the *Practitioner* contains an article by Dr. W. Soltan Fenwick which concludes as follows:

At the present day every imaginable symptom that can in any way be connected with the digestive organs is immediately considered as an indication for the use of lavage, and we find that not only are chlorosis, atonic dyspepsia, and the gastric crises of ataxia subjected to this treatment, but even cases of reflex vomiting are supposed by some to necessitate the employment of the douche. But it is obvious that in those

cases where the treatment fails to do good it is extremely likely to do harm, since, as Leube pointed out, it has the effect of removing those products of digestion whose manufacture has caused the stomach a considerable amount of labor. And for my own part I fail to understand how washing out the organ in a case where the normal amount of secretion proves insufficient can possibly increase its digestive powers; or the lavage of the stomach prevent the occurrence of symptoms which are wholly dependent on organic disease in another organ remotely situated. In one case of tabes dorsalis, accompanied by exceedingly severe gastric crises, I had the stomach washed out every day for some weeks and the state of digestion carefully watched; but beyond the fact that the symptoms of the disease grew steadily worse, I could detect no material alteration in the condition of the patient. In like manner, the few cases of atonic dyspepsia and chlorosis which I have treated by lavage have, without exception, proved exceedingly rebellious and only improved when subjected to the more ordinary course of medical treatment. I would therefore conclude by saying that although lavage is an invaluable remedy in certain cases of gastric disease, its indiscriminate employment in every case of disorder of digestion will prove a curse rather than a benefit, and will eventually throw discredit upon the whole method of treatment.

**To Contributors and Correspondents.**—The attention of all who purpose favoring us with communications is respectfully called to the following:

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Original Communications.

ON THE SCOPE OF ORTHOPÆDICS.

By F. BEELY, M. D.,  
BERLIN.

IN the introduction or preface of treatises upon orthopædic surgery, authors usually give a concise definition of this specialty and a short enumeration of the diseases which come under the head of this department. In some essays that have appeared within the past few years the necessity for so doing has been emphasized. Dr. N. M. Shaffer, for example, delivered an address before the International Medical Congress at Berlin in 1890 entitled, *What is Orthopædic Surgery?* Dr. Gibney also read a paper before the American Orthopædic Association, at its fifth annual meeting at Washington, in 1891, called *Orthopædic Surgery; its Definition and Scope*,\* and Dr. Shaffer's reply was published in the *New York Medical Journal* for November 14, 1891. There seems to be no definite agreement as to the true definition of this specialty. Authors in different countries vary very materially in their views upon this subject. Shaffer, for example, says: "Orthopædic surgery is that department of surgery which includes the prevention, the mechanical treatment and the operative treatment of chronic or progressive deformities, for the proper treatment of which special forms of apparatus or special mechanical dressings are necessary." Dr. Gibney, whose paper is essentially a critique upon Dr. Shaffer's address, agrees with him in the main, but he does not think that the scope of orthopædics should be limited from the standpoint of mechanico-therapy. Acknowledging Shaffer's definition to be to a great extent the true one, Gibney omits, however, the qualifying phrase of the definition, which says: "For the proper treatment of which special forms of apparatus, etc., are necessary." Dr. L. A. de Saint-Germain, in his *Chirurgie orthopédique*, defines the problem thus: "Le redressement, la rectification, des difformités." But we find in his book sections on obesity, malformations of the ears and of the teeth, hypertrophy of the tongue, hare-lip, navi, strabismus, etc. Dr. E. H. Bradford and Dr. R. W. Lovett, in their treatise on *Orthopædic Surgery*, 1890, without giving the definition, say: "Orthopædic surgery should include the prevention as well as the cure of deformity." Besides Pott's disease, club-foot, lateral curvature, bow-legs, the diseases of the joints, etc., they include spondylolisthesis, congenital dislocation of the hip, webbed fingers and toes, and cerebral paralysis, but omit to cite the deformities resulting from fractures, dislocations, and burns. Dr. Schreiber, in his *General and Special Orthopædic Surgery (Allgemeine und specielle orthopædische Chirurgie, 1888)*, calls orthopædics "the science of the deformities of the human body." Dr. Hoffa, in his treatise, limits its sphere to those deformities of the body which appear as deviations of posture and stature of the skeleton. The purport of these two books is very similar. Hoffa in-

cludes prosthesis under orthopædics, which means the manufacturing of all apparatus and bandages. Both authors devote special chapters to the treatment of orthopædic diseases following fracture or dislocation of bones, traumatic lesions and burns of the soft parts, and inflammation of the soft parts. There are numerous other examples, but the foregoing quotations may be sufficient. It is impossible in so short an article to indicate the various definitions given by different authors. The question therefore arises, Is it necessary or even advisable to confine or limit the realm of orthopædic surgery? Possibly it would be best to leave it all to gradual development. Should we not rather hold fast to the present opinion, and, without regard to principles, study from the various sources those diseases the treatment of which is generally accepted by orthopædists?

It may be of some interest to glance into the history of orthopædic surgery—viz., as to how it originally developed—thus trying to gain further insight into its nature, and become familiar with methods which may lead us to accord to it proper rank among the specialties. General medicine has been divided into specialties, because it has been impossible for one man to acquire a proficiency in all. This separation has been due to different circumstances. It was necessary that either one particular organ or a restricted region of the body should be studied—for example, the nose, throat, or larynx; or a specified system of tissue which the specialist should select as his province—as that of the skin, the nerves, etc.; or therapeutical measures the application of which required special dexterity; or else appliances, like massage, gymnastics, and electrotherapeutics. The department of the last named is, of course, not limited. One is at first uncertain as to which category of specialties orthopædy belongs. From the many definitions attempted, it appears that great effort has been made to secure for it a firmly planted position in the department of surgery. The fact that scientific authors and practitioners desire to do so seems evident. On an anatomic-physiological basis, a scientific system may be more clearly erected. Pathological anatomy, symptomatology, diagnosis, and therapeutics are more clearly allied to it, while it is difficult to find a systematic scientific classification from the therapeutical point of view. The practitioner, to whom the scientific point of view is not of much importance, desires to appear to the public not so much as practicing therapeutical methods as that of being an authority upon the treatment of a special class of diseases, so that he need have no fear of being supplanted in order that his patient may have change of treatment. We can not admit that this view of the subject is the right one, as it is not consistent or in accordance with historical development, as least so far as Germany is concerned, and I think that German conditions are especially suitable as illustrating this point, as Germany has had for so long a time the advantage of a thoroughly instructed medical profession of the highest scientific order. If we glance at the history of orthopædic surgery in Germany, as sketched by Hoffa, our attention is especially drawn to the names of Heine (1770-1838) and to Helsing. Hoffa says of the

\* *N. Y. Med. Jour.*, Nov. 7, 1891.

former: The name of Heine takes the first rank among the founders of orthopædia.

Johann Georg Heine, of Württemberg: "His establishment was the prototype of all others"; and, regarding the latter (Hessing), we are indebted to him, a skillful mechanic, for the knowledge of all kinds of splint-capsule apparatus, and various apparatus for supporting the spine. Heine was in early life an apprentice to a cutler and afterward to a manufacturer of surgical instruments. Neither of these men belonged to the medical profession, nevertheless they greatly advanced orthopædic surgery, and have become famous beyond the confines of Germany. Their reputation was due to their skillfulness in the use of mechanical instruments. Heine devoted himself exclusively to the application of orthopædic apparatus, and scorned to make use of gymnastic exercises or subcutaneous tenotomy, invented at that time by Stromeyer. He equally despised the aid of medicine administered internally (see *Bibliographisches Lexicon*, by Goult). Both of these men have proved that eminence and success, not surpassed even by the most celebrated contemporary surgeons, may be acquired by the adoption solely of mechanical methods. It is not to be wondered at that Heine, as he had been deprived of the advantage of medical instruction, and also on account of his eccentric therapeutical theories, should have made many mistakes, especially as he often ventured upon the treatment of diseases when the proper mechanical instruments could not be procured. On account of his general success he became extremely arrogant, and he practiced general medicine irrespective of all professional ethics. These shortcomings, however, did not detract from his real merit, save that he did not during his lifetime receive full credit for his valuable services. Hoffa continues: "He steadfastly adhered to his conviction that in orthopædy mechanical methods should alone be adopted. Many of his disciples and imitators have practiced his teachings, and thus great reproach rests upon Heine for having delivered orthopædy into the hands of the manufacturers of instruments. The medical profession, consequently, became averse to treating deformities, and so gradually, up to the present time, the majority of them prefer to relegate their patients to the department of the bandagist."

Upon this point I differ with Hoffa. Heine, I think, was on the right track. Members of the profession who do not appreciate the value of mechanical apparatus are to be blamed for this decadence, for they leave to the bandagist the most important department of therapeutics. Mechanical treatment is, and ever will be, the very essence of orthopædy. Upon that it stands or falls. If mechanical treatment be left out, orthopædy becomes either operative surgery or gymnastics and massage. The orthopædist must, of course, take personal supervision of the mechanical treatment, and not simply prescribe the apparatus as the practitioner prescribes his medicine. The apparatus should be made under his special direction, and he must assume the entire responsibility of its application and use. Under these conditions alone can he hope for continual development and progress. What would be thought of a surgeon who restricted his practice to diagnosis and prescription,

and turned his patient over to the nurse for mechanical treatment? What the patient demands of the surgeon he should require of the orthopædician. From the difficulty of defining the line between orthopædy and surgery there arose, according to Hoffa, the term "orthopædic surgery." As I have expressed my opinion to the effect that mechanical treatment is the essence of orthopædy, I should therefore prefer to have it called *mechanico-therapy*. The last term would be the more significant, but in Germany this term is used for "cures by motion" or gymnastics and massage. General surgery, then, would be divided into mechanical surgery and operative surgery. As there are some physicians who prescribe only internal medicine and do not perform surgical operations, so there are others who practice both internal and external treatment with equal skillfulness. Some surgeons undertake operative work only, others mechanical only, while many others practice both combined. An entire separation could be practicable only in large cities.

The consideration from this standpoint leads to the question, What diseases belong to the department of orthopædy and which of them belong to general surgery? Unfortunately, I do not know to what extent Heine carried his experiments. As to Hessing, we know that besides treating deformities, he also treated joint diseases, some cases of dorsalis, and also fractures successfully. We have seen, therefore, that from the above-mentioned illustrations the criterion of orthopædy is the mechanical treatment; and the representatives of orthopædic surgery, and other physicians who have had equal advantages show a predilection for solving mechanical problems. By this means patients may be supplied with apparatus from the technical and therapeutic point of view. The orthopædician should undoubtedly be placed upon equal footing with other specialists, in order that the sufferings of mankind may be alleviated. He may lay claim to the treatment of fractures, as well as to mechanical treatment of spondylitis; he may undertake the treatment of hernia as well as curvature. This should be taught in the universities, and it would then lead to a higher estimation of, and to more rapid progress in, mechanical surgery. Young doctors would then have the opportunity of studying the mechanical as well as the operative treatment of deformities, and would be glad to avail themselves of it, as they have hitherto been unable to do, notwithstanding that the professors have had the desire for imparting the knowledge. The number of operations in the treatment of deformities would be greatly diminished, as there are, as a matter of fact, very few that could not be avoided, if relatively simple mechanical means could be correctly and promptly administered. Nearly every osteoclasia or osteotomy in genu valgum or rhachitic curvature of the lower part of the thigh; almost every bloody operation in pes equino-varus; in fact, nearly every violent redressment of angular ankylosis of joint disease, has been necessarily performed because of incompetent knowledge of mechanical treatment.

**Resorcin**, in five- to ten-grain doses, dissolved in plenty of water and flavored with orange-peel syrup, is reported to relieve the nausea and depression following the excessive use of alcoholic stimulants.—*British and Colonial Druggist*.

THE INFLICTION OF THE  
DEATH PENALTY BY MEANS OF ELECTRICITY.

BEING A REPORT OF SEVEN CASES.

With Remarks on the Methods of Application and the  
Gross and Microscopical Effects of Electrical Currents of Lethal Energy  
on the Human Subject.

By CARLOS F. MACDONALD, M. D.,

PRESIDENT OF THE NEW YORK STATE COMMISSION IN LUNACY;  
PROFESSOR OF MENTAL DISEASES IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE;  
LECTURER ON INSANITY IN THE ALBANY MEDICAL COLLEGE.

(Concluded from page 509.)

AUTOPSIES.

*William Kemmler.*—The autopsy, held about three hours post mortem, was by verbal direction of the warden officially in charge of the writer, and was performed by Dr. E. C. Spitzka, Dr. George F. Shrady, and Dr. W. T. Jenkins, of New York, and Dr. C. M. Daniels and Dr. George E. Fell, of Buffalo, N. Y. Notes were taken by Dr. Shrady, from which the following is compiled :

Body fairly well nourished. Rigor mortis marked, particularly in the muscles of the jaw, neck, and thorax, and gradually extending from above downward, involving the feet and legs last. Post-mortem discoloration existed over lower portion (posterior and lateral aspects of trunk) of body, and extended up as far as the anterior axillary line, also on the pendent surfaces of the upper and lower extremities. The upper extremities were partly flexed and rotated outward, the nails showing post-mortem lividity. There was a seminal discharge, which, on microscopic examination, was found to contain a large quantity of dead spermatozoa. There was marked post-mortem discoloration of the forehead, about an inch in width, corresponding with the position of the strap, beginning at the hair on the left side and extending to the hair line on the right side. A corresponding discoloration from the pressure of the chin strap was also noted. There was an oval depression of the scalp upon the vertex, due to the pressure of the electrode, beginning at the anterior hair line and measuring four inches in its long and three inches and a half in its short diameter. Anterior to the posterior portion of the depression and in the immediate line there was a vesication an inch and a half in length, very superficial in character, crescentic in shape, and upon which the hair appeared to be slightly scorched. On the small of the back, corresponding to the level of the fourth sacral vertebra below and second above, four inches and a half in vertical diameter and four inches and a half in transverse diameter, was a burn, presenting four concentric zones, of which the outermost had a pale area, corresponding to that of the rubber cap of the electrode, and one fourth of an inch in diameter.

Succeeding this was a vesication, partial below and complete above, about an inch in diameter above and one third of an inch below.

Then followed another zone, which was in its upper third a complete eschar, black in appearance, and in its lower part showed desiccation of a greenish-brown color. The last or inner zone showed a number of vesicles, chiefly peripheral, and below the center was a black eschar, half an inch in its vertical and five eighths of an inch in its transverse diameter. Above was a tongue-shaped, pale area, with a lateral projection to the left of the median line, extending about two inches, and an upper projection in the dorsal furrow, which was more sharply pointed, and which on its periphery showed a reddened portion, with here and there vesication. In addition, the back showed a number of depressions produced by the folds of the

shirt and suspenders, such as are commonly found in dead bodies lying on the back.

On incising the skin over the sternum, the blood which escaped was unusually dark and fluid, and remained so on exposure. The muscles of the thorax were of the usual color. "Tardieu spots" were noticed on the posterior border of the lower lobe of the left lung. When placed in water, more than half of the lung floated above the surface, showing a marked emphysematous condition. The bronchi were normal in appearance, and contained mucus and air bubbles. The right lung was adherent throughout to the diaphragm. In the middle lobe of this lung there were numerous well-marked "Tardieu spots." The heart weighed five ounces and three quarters; its valves and substance were normal in appearance, and its ventricles were empty. The stomach contained a pint of undigested food. The blood from the cut surface of the liver was of a dark-crimson hue. The gall-bladder was distended with bile. The spleen was normal in size and appearance. The left kidney weighed three ounces and a half, and the right three ounces; both were markedly congested. There was no vermicular action of the intestines on exposure to the air or on irritation. The bladder was contracted.

The scalp, on being removed, showed the outer aspect of the vertex of the skull to be in a desiccated condition, corresponding with the site of the electrode as previously noted, but of a larger area, being four by four inches, the zone of the scalp being only two and a half by three inches, the long diameter being antero-posterior. On removal of the skull-cap, the dura was normal in texture, somewhat dull in color, particularly over the area corresponding with the zone of contact. In the pre-Rolandic region the meningeal vessels, measuring along the convexity antero-posteriorly four inches on the left side and three on the right, were filled with carbonized blood. On the internal aspect of the calvarium the meningeal vessels in the dura and in their contents appeared to be black and carbonized. The carbonized vessels were so brittle that their ends were torn off with the calvarium and presented a broken, crummy appearance. This carbonization was limited in an abrupt manner. The other meningeal vessels in the region corresponding to the outer burn, previously described, contained blood of a dark-crimson hue. In the narrowest portion of this region was seen, a little posteriorly, in the median line, a dark discoloration sending out a right lateral prolongation three fourths of an inch in the direction of the longitudinal sinus, and in width seven eighths of an inch. Over the left cerebral hemisphere, one third of an inch to the left of the median line, there was a deep carbonized spot corresponding with the desiccated portion of the calvaria. The pia and gyri were of a pale-buff color; the rest of the cerebral cortex was normal in appearance. While observing this anæmic area it was noticed that its blood-vessels began to fill. The pia and arachnoid on the convexity of the brain were perfectly normal. An interesting fact was observed on handling the pons and medulla, in that they were found to be warm. By a thermometer inserted in the fourth ventricle, the temperature was noted at 97° F. The area of this temperature corresponded with an area of temperature on the back of the neck which was noted at 99° F., three hours post mortem, the temperature of the room being 83° F. The smaller vessels of the pia were ectatic. *Capillary hemorrhages were noted on the floor of the fourth ventricle, also in the third ventricle and the anterior portion of the lateral ventricle. The circumvascular spaces appeared to be distended with serum and blood.* The brain cortex in the area of contact was sensibly hardened to one sixth of its depth, where there was a broken line of vascularity. The vessels over the corpus striatum showed enlargements in different parts of their ramifications. The pons was slightly softened.

The spinal cord was removed entire, but showed no gross appearances of pathological condition. Portions of the brain and spinal cord were preserved for purposes of hardening and microscopical examination. The blood taken immediately after death showed, under the microscope, a markedly granular condition, almost suggesting an electrolytic dissolution of the red corpuscles.

A preliminary microscopical examination of portions of the brain and spinal cord, including specimens from all the cerebral lobes of both sides, segments of the cervical, dorsal, and lumbar regions of the spinal cord, with the connected nerve groups, was subsequently made by Dr. Spitzka, who states as follows:

The brain, spinal cord, and peripheral nerves appeared structurally healthy in every portion examined, except in the area corresponding to the discolored (anæmic through extreme contraction of vascular channels) area of the Rolandic and pre-Rolandic regions, the ventricular surfaces, and the pons and medulla oblongata. The latter, which had been the seat of a remarkable post-mortem preservation of a temperature approaching that of the normal human body, were distinctly softer than the observer has been accustomed to find these parts in autopsies on persons of Kemmler's age, and performed so soon after death. The hæmorrhagic spots in the fourth ventricle, which were strongly marked, were not accompanied by signs of parenchymatous rupture of larger vessels. Hence they may be regarded as having the same significance as the "*taches de Tardieu*" found on the surfaces of other organs—notably, the heart and lungs.

The peculiar softened vesicular zone of tissue underlying the outermost layer of the cerebral cortex being very fragile, will require extreme care in hardening and manipulation to enable me to obtain reliable specimens. It is noteworthy that this "destruction line" runs parallel to the free surface of the brain and does not "dip" with the sulci.

Examination of the fresh specimen revealed the existence of vacuoles (probably gas bubbles) in the ganglion cells and in the parenchyma of the "destruction line." From the fact that no hæmorrhages had occurred in this softened area, it is a just inference that it was produced after life had become entirely extinct, for the continuance of a blood circulation in a softened brain area is incompatible with the bloodless appearance already noted and the absence of capillary hæmorrhages in this very district while they were present in those remote from the site of the electrode.

A more minute analysis will be completed, but can not be reported until some future time.

That the "cooked" appearance of the muscular tissue of the back beneath the site of the electrode, and the desiccation of the skull and so-called "carbonized" state of the blood-vessels on the internal aspect of the calvaria over the area corresponding to the zone of contact, were due to the unduly prolonged second contact, together with failure to properly moisten the electrodes, there can be no question, no such results having been observed in any of the subsequent cases, the surface lesion in these latter being limited to superficial vesication of the skin at the points of application of the electrodes, as will presently appear.

All of the subsequent autopsies, including the microscopical examinations, were made by Dr. Ira Van Gieson, of the Pathological Laboratory of the College of Physicians

and Surgeons, and are here described substantially in Dr. Van Gieson's language.

*Schichiok Jugigo.*—The post-mortem examination in this case was held four hours after death. The pupils were alike and moderately contracted. The body was well nourished and unusually well developed. The anterior epithelial cells of the cornea had desquamated from the central portion by the action of heat. There was a bulging forward of the sclera of the left eye at the left sclero-corneal junction. Conjunctiva anæmic. The scalp and skin covering the neck had a dull, purplish hue. The skin of the anterior surface of the body was not discolored or ecchymosed. At the flexure of both elbows were a number of symmetrical linear ecchymoses, which were more marked on the right side. Also a curved, narrow ecchymotic line just below the outside of the right nipple. These probably were caused by the straps. At the posterior surface of the right knee-joint, and on the posterior and inner and upper surface of the calf, the epidermis was raised, wrinkled, and folded. At the flexure of the knee joint the epidermis had been torn away to the extent of about an inch in diameter. The right lower extremity was flexed and bent more to the median line than its fellow. There is a slight discharge of thin, milky fluid from the urethra and some still remaining in the canal. A sample of this fluid was taken for microscopical examination. Post-mortem rigidity well marked except in the arms, where it was only slight. The whole posterior surface of neck, trunk, arms, and lower extremities was of a dull, purplish hue. There were a few slight blisters on both temples, and both cheeks and eyelids. There were raised whitish streaks on both sides of the neck, just below the angle of the jaw.

The trunk was opened by a straight incision from the top of the sternum to the pubes. The fat was an inch thick over the abdomen. Muscles red and firm. Diaphragm at left side was found at the level of the sixth intercostal space, and on the right side at the fifth intercostal space. Portions of small intestine were taken for microscopical examination.

Examination of heart: Auricles and ventricles flaccid and in diastole and filled with fluid blood. The larger vessels were tied and the heart removed. The left ventricle was well filled with fluid blood but no clots. The auricles were the same. The blood was of the same color in the left ventricle as in the right. Valves normal. On opening the vessels, a large quantity of dark-colored liquid blood escaped, half filling the pleural cavity. There were no pleural adhesions. Lungs perfectly healthy, but slightly congested.

The spleen was found to be of normal size, the capsule smooth, pulp firm, and uniformly filled with blood, and the arrangement of the Malpighian bodies and splenic connective tissue entirely normal.

The pancreas was perfectly normal and a portion removed for microscopical examination.

Liver entirely normal, and a portion was also removed for microscopical examination.

The gall-bladder was filled with bile.

Left kidney: The capsule was non-adherent. It was rather large and the cortex of normal thickness. The kidney was uniformly injected and the markings in the cortex were normal as to number and arrangement. The right kidney was in the same condition.

The stomach was empty, the mucous membrane pale; the rugæ were well marked and perfectly healthy.

The intestines were healthy. The small intestines were filled with semi-fluid fæces. The large intestines showed the same condition.

The urinary bladder was normal and half full.

Examination of brain: The brain was exposed by a straight incision of scalp over the vertex from ear to ear, and saw cuts through the skull at a slight angle and at the level of the eyebrow. The scalp showed several old scars, and was slightly less adherent under those portions where the electrode was attached. The skull was symmetrical. The dura mater was normal and the vessels moderately dilated. The longitudinal sinus was found to be normal and contained some fluid blood. The brain was removed in the usual way. The pia mater was uniformly thin and transparent; the vessels in a medium state of congestion; subpial fluid small in amount. The blood was everywhere fluid in the meshes of the pia mater. There was no apparent difference in that portion which the electrode covered. The vessels at the base were perfectly normal. The ventricles contained a small amount of clear fluid. The roof and floor of the lateral ventricles were normal. The ependyma was smooth and transparent. White substance firm. Gray matter normal in every respect. Floor of the fourth ventricle at the upper half contained some dilated vessels, and on the left side there were a number of minute, radiating petechial spots from one to two millimetres in diameter. (See Fig. 1.)

The spinal cord was exposed in the usual manner. The external appearance of both cord and membranes was entirely normal, and the vessels containing, if anything, even less blood than usual, due, probably, to the short time that had elapsed between the occurrence of death and the holding of the autopsy. Sections half an inch apart showed nothing abnormal. A portion of both sciatic nerves was taken for microscopical examination.

Owing to the great length of time necessary to make this autopsy as completely and minutely as was done, and the subsequent careful microscopical examinations, it was not considered necessary to examine the brain and spinal cord in the other cases, especially as nothing of any importance had been observed in these organs in this case.

*Harris A. Smiler.*—Posterior surface of the body was of the same color, and also showed the same blisters as in the case of Jugigo. The left leg showed the same state of contraction.

The body was opened by the long, straight incision, as in the case of Jugigo. The diaphragm was found at the left side at the sixth intercostal space and on the right side at the fifth intercostal space. The left lung was slightly adherent at the apex. The heart was rather small. The left ventricle was somewhat firmer than the right, which latter was a little flabby. The auricles were distended with fluid blood. The right ventricle was empty and collapsed. The apex of the left lung was small and shrunken and retracted, and contained a few small, scattered, dense, tubercular nodules, some of which were calcified. Otherwise the lung was normal and resembled the preceding case. Right lung shows the same set of changes, but not so marked. Small ecchymotic spots (Tardieu's spots) were observed under the pericardium on surface of left ventricle. The walls of the ventricles were of normal thickness. There were signs of an old endocarditis below the aortic valves. All the valves were healthy.

The spleen was small and the pulp soft and normal.

The pancreas was normal.

The liver was normal both in size and texture.

The left kidney was greatly hypertrophied and the capsule non-adherent. The cortex was somewhat thickened and the markings distinct and regular; moderately congested. The right kidney was small, two and a half by three quarters of an inch in size, and weighed forty-eight grammes—less than an ounce and three quarters. The tissue was normal, but the kidney was apparently congenitally small.

*Intestines.*—Descending colon was filled with gas; ascending colon and small intestine pallid and contained semi-fluid material.

Stomach contained undigested food, potatoes, etc. Mucous membrane pale and coated with a thin layer of slimy mucus. Bladder distended with urine. Walls and mucous membrane normal.

Examination of brain and cord deemed unnecessary. The blood was fluid everywhere and darker than normal.

*Joseph Wood.*—Autopsy held at 1.25 p. m.

Body presented same appearance as in preceding cases. There was the same contraction of the legs and the same general appearance as in the others. Same condition of epithelium of cornea.

Median incision made as in other cases. Diaphragm attached to fifth intercostal space on both sides. There were half a dozen scattered petechial points found under the pericardium, half a millimetre in diameter. On the anterior surface of both ventricles and on the posterior surface of the left ventricle were five scattered similar points. On the posterior surface of the right ventricle were three similar small points and one larger, three millimetres and a half in diameter.

Heart normal in size and condition of ventricles the same as in the case of Smiler. Both lungs were free from adhesions. The right lung, bronchi, pulmonary vessels, and lung tissue were normal, but somewhat more pigmented than usual. The substance of the lung was dry and dark pink in color. Heart muscles pale and firm and of normal thickness. All the valves were normal.

Spleen was normal in size and dark red in color, and showed two thickened white patches on capsule. The pulp was firm.

The pancreas was normal.

The liver was normal in every respect.

Both kidneys normal in every respect.

Nothing abnormal was found in the intestines.

The gall-bladder was distended with normal bile.

The urinary bladder was of normal thickness, but the mucous membrane was considerably congested.

The brain and cord were not examined.

*James J. Slocum.*—Autopsy held at 1.45 p. m. There were the same blisters and external appearances as in the others. There was also the same appearance of cornea. Median incision was made as in the other cases.

*Heart.*—Petechial spots scattered about as in the other cases, and were also observed under the pulmonary pleura. The left ventricle was firmly contracted, while the right was flabby. Both auricles, especially the right one, were filled with fluid blood. The left lung was free from adhesions. The upper lobe of right lung was slightly adherent. The left lung was in the same condition as the others, but slightly œdematous. The right lung was in the same condition. There was a well-marked large group of petechial spots at the center of anterior surface of left ventricle.

The spleen was of normal size, with the pulp soft, of dark-red color and somewhat congested.

Pancreas was normal both on the surface and on section.

The gall-bladder was half full of bile and the common duct patulous.

The liver was normal in every respect.

The left kidney was very much congested, but normal in all other respects.

The right kidney was in a similar condition.

A careful examination of the intestines showed nothing abnormal.

The bladder was collapsed and normal.

The trachea was normal.

## MICROSCOPICAL EXAMINATION.

The practical results of the microscopical examination are, that the passage of the electric current through the body is attended with no recognizable changes in its tissues or organs, excepting the local thermic changes in the skin at the points of application of the electrodes and some minute petechial spots on several of the organs.

Such a summary of the examination, however, seems insufficient without adding that it was determined by most exhaustive and modern investigation, and as there are apparently no recorded examinations of similar cases in medical literature, it seems not inappropriate to give the detailed report subjoined, showing in what way and to what extent the tissues were examined.

Specimens were taken from all four of the subjects, but the material from the Japanese criminal was especially selected for minute study, as it could be obtained the soonest after death.

Notes about the technical preparation of tissues are added at the conclusion of the report.

*The Examination of the Cells in General.*—For this purpose the ciliated cells of the trachea, the liver cells, and the ganglion cells were studied especially with the oil-immersion lens. The physical properties of the protoplasm are in no way changed. The arrangement of the protoplasm, its volume, consistency, its behavior with light and staining reagents, are not at all different from the ordinary cell body. The same may be said of the constituent elements of the nucleus. None of the cells in any of the tissues examined show any signs of mechanical violence, such as tearing, fracture, or disintegration of the protoplasm. Neither does there appear to be any chemical change in the nucleus or cell body, as far as can be determined with micro-chemical methods. (The cells thus studied were prepared with solutions of corrosive sublimate, and also osmic acid.)

*The Blood.*—The blood cells are not damaged in any way by the current. The red cells have their normal size and shape. The white cells are uniformly spherical and have the usual arrangement of the nuclei. The blood was very perfectly preserved, even the blood plaques being unchanged.

*The stomach, small intestine, and kidney* are unchanged, with the exception of a slight amount of post-mortem degeneration in the parenchyma cells. The stomach shows the appearances of functional activity.

*The liver and pancreas and spleen* show no changes.

*The Muscular System.*—The smooth muscles, studied from the gastro-intestinal tracts and the heart muscle fibers, are unchanged.

In sections of the eyelid lying directly beneath the electrode the voluntary muscle fibers are normal.

*The blood-vessels* are not altered. *The lungs and genital organs* were not examined microscopically. The fluid ejaculated from the urethra in the case of the Japanese criminal does not show spermatozoa.

*The central nervous system* was examined with especial care. It has recently been determined that, during periods of muscular fatigue or prolonged muscular exertion, certain of the motor-ganglion cells are diminished in volume, which is recovered again during periods of muscular repose. Speaking roughly, this shrinkage of the ganglion cells during muscular fatigue represents a sort of mechanical equivalent of the work done by the muscles. Hodge (*Am. Jour. of Psychology*, May, 1888, 1889, and 1891), in inducing experimentally the effects of fatigue in ganglion cells by the prolonged action of weak electrical currents, found that the ganglion cells suffered a vacuolation, shrinkage in the volume of the cell body, and a still greater reduction in the size of the nucleus. This diminution of the

ganglion cell was tangible enough and could be measured, and in some cases in Hodge's experiments with the current on cats the nucleus shrank to 43.9 per cent. of its original bulk.

Although it could hardly be expected that there would be time enough for the ganglion cells of these criminals to show traces of the intense muscular contractions, yet the ganglion cells of the central convolutions and the anterior spinal cornua were very carefully examined to see if there would be any shrinkage coincident with the expenditure of so great an amount of muscular energy as was manifested during the contacts.

The ganglion cells in these regions, however, as far as can be determined by careful comparison with sections from the same regions in other ordinary healthy subjects, seem to be normal in size, or at least do not show any striking reduction in volume. A slight shrinkage may be present, but it would be almost impossible to determine it from the lack of a normal standard to make measurements with. Concerning this suspected change in the ganglion cells, then, it may be said that if there is any shrinkage at all, it is of very limited extent.

At the autopsy some minute petechial spots were found on the floor of the fourth ventricle (Fig. 1).<sup>\*</sup> Microscopically, these spots are small masses of extravasated red blood-cells, situated, for the most part, in the perivascular spaces just beneath the ependyma.

The diagrams show the distribution and character of those hæmorrhages well enough, so that we may omit detailed description of them. A few of the extravasations are more deeply situated and have a more significant position with regard to the important nuclear groups in the medulla. Fig. 2*a* shows one of the hæmorrhages just on the outskirts of the sensory vagus, and other smaller ones close to the hypoglossal nuclei. The extravasation near the vagus is confined by the perivascular space of the median lateral artery of the medulla, which takes the course of the dotted line *x, y*, in Fig. 2.

These hæmorrhages look as if due to the passage of blood along the perivascular spaces, and out into the tissues after rupture of a small vein or capillary, but whether any especial significance should be attached to these hæmorrhages, or whether they are caused directly by the current, or by intense muscular tension, or by manipulation in removing the brain, are questions extremely difficult to decide about.

*The Peripheral Nerves.*—The sciatic nerves from both sides were examined without finding any change or difference between the sciatic of the electrode side and its fellow.

The delicate structures of the *retina* lying so close to the electrode are not altered.

*The skin beneath the electrode* is but slightly changed. The epidermis is absent or raised up from the corium and has a dried-up appearance. The corium, structurally, is nearly normal; the connective-tissue nuclei are not shrunken and stain well, but the connective-tissue bundles and fibers seemed changed chemically and behave abnormally with certain staining reagents. The sweat glands are degenerated to a considerable extent; they have a desiccated appearance.

It would then appear from this examination that, beyond the scalding effects of the electrodes, electric currents passed through the body in this way produce no change in the body except minute petechiæ, and it is doubtful if these are not some indirect or secondary consequence of the current. The results of the microscopical examination of the two remaining subjects—Loppy and McElvaine—are corroborative in every way of this examination.

It seems proper to add that the central nervous system of only one of these four cases was removed, because nothing was

<sup>\*</sup> The plates are from drawings by Dr. Van Gieson.

found in it which would receive any further elucidation from the examination of the other three cases.

#### METHODS OF THE PREPARATION OF THE SPECIMENS.

*The Blood.*—Two drops from a glass rod dipped in the freshly cut right ventricle were received in a one-per-cent. aqueous osmic-acid solution.

The sciatic nerves were prepared in the same medium by gently pulling short fasciculi out of their lamellar sheaths, allowing the acid to penetrate.

*The Central Nervous System.*—Thin shavings of the convolutions and of the cervical spinal cord were placed in alcoholic and aqueous solutions of corrosive sublimate of different strength for periods of time varying from an hour to several days. Exceedingly small portions of the gray matter were also hardened in Fleining's osmic-acid mixture and in one-per-cent. osmic-acid solution for half an hour. All of the specimens were subsequently hardened in eighty per cent., and then in strong alcohol.

Still other portions of the convolutions were scraped gently with a sharp razor, so that the gray matter was reduced to a thick pulpy broth on the edge of the razor. This pulp was then shaken into exceedingly fine fragments in osmic acid and sublimate solutions, so that the fixation of the ganglion cells would be as nearly as possible uniform and instantaneous. (Incidentally, attention may be called to this method as giving very good results for ganglion cells, and being much better than the ordinary methods of hardening the cortex in blocks, no matter how small.)

The medulla and portions of the cord were also hardened in Müller's fluid in the usual way. The *trachea*, *thoracic* and *abdominal* viscera were prepared in sublimate solution, and also with strong alcohol in the ordinary way. Portions of the *spleen*, *pancreas*, and *liver* were also injected interstitially with osmic-acid solution. The eyeball, *eyelid*, and *singed portions* of the *integument* beneath the electrodes, were prepared with Müller's fluid.

All of these variously hardened portions of the tissues were imbedded in celluloid and sections stained appropriately with several different methods, such as Weigert's method, double staining with hæmatoxylin and eosin, and also with the picro-acid fuchsin method.

*Martin D. Lippy.*—Autopsy held as soon as practicable after breaking of the last current. Subject somewhat below the medium stature. Body well nourished. Muscular system well developed. Rigor mortis almost completely, if not entirely, absent, except in the right leg, where there is sufficient muscular rigidity to hold the leg slightly adducted and flexed at the knee joint. The mouth and nostrils are perfectly natural, and show no traces of the extrusion of fluids or frothy material. About a drachm of viscid fluid, wetting the skin of the pubic region, has escaped from the urethra.

There are no discolorations, contusions, or other marks on the skin, except in two places—viz., (1) at the flexure of the right knee, where the lower electrode was applied, and (2) upon the cheeks, corresponding to the position of one of the restraining straps. The unexposed surfaces of the skin are everywhere else smooth, white, rather thin, and delicate in structure, and show no settling of blood in the dependent portions of the body.

At the flexure (or back part of the knee joint), where the *lower electrode* was applied, there is a diffuse reddish discoloration of the skin about three inches and a half by five inches in diameter. This region of the skin shows a very moderate, superficial, irregular separation of the thin outer scarf skin or

epidermis from the true and thicker skin beneath. The epidermis or scarf skin in this region is raised up and corrugated, and it can be easily rubbed off with slight force. When the whole thickness of the skin is cut through with a knife, it can be seen that this change is quite superficial, affecting the outer scarf skin only, and does not damage the corium or true skin beneath to any appreciable extent.

The corium or true thicker skin underlying the electrode region is soft, pliable, not desiccated, and seems to be normal in every way, except that it is somewhat congested, which produces the reddish discoloration in this region.

The layer of fat beneath the skin in the electrode region is in no way changed or damaged.

The *head electrode* has left no traces upon the skin. The forehead and scalp beneath the electrode are perfectly white and natural, and there are absolutely none of the superficial alterations referred to above at the knee joint.

There is redness and swelling of both cheeks just beneath the eyes, which is very moderate in extent and not enough to make any distortion of the face. This was occasioned by pressure against one of the leather restraining straps during the periods of muscular activity when the current was applied.

The right eye had been lost some time previously during life. The eyelids are closed; skin of eyelids intact. Anterior corneal epithelium of the left eye cloudy, but not detached. The eyeball is perfectly natural; it has the proper tension and contour.

The interior of the mouth is normal. The tongue and the teeth show no signs whatsoever of injury.

The body was opened in the usual way. The abdominal organs were critically examined first, then the thoracic viscera, and finally the brain and upper portion of the spinal cord.

The *stomach* is normal; it is much contracted, rather small; mucosa pallid; fundus smooth; pyloric extremity folded.

The *small intestine* is normal, contracted, upper portion nearly empty, lower portion partially filled with semi-fluid faecal matter.

The *spleen* contains, just beneath the normal capsule, several larger and smaller hæmorrhagic spots, from one millimetre to three millimetres in diameter, such as are not infrequently found after death from a variety of causes. The substance of the spleen is normal.

The *pancreas* is normal in size and texture.

The *liver* is normal in size, and uniformly filled with blood; cut surface smooth, stroma and parenchyma unchanged. *Gall-bladder* normal; partially filled with bile.

The *kidneys* are of medium size; capsules non-adherent; vessels well filled; the cortex is normal in thickness, and has its constituent elements properly arranged.

The *suprarenal capsules* are unchanged.

The *urinary bladder* shows no abnormalities; it is much contracted and its mucosa pallid.

*Heart.*—The left ventricle is firmly contracted and empty; both auricles and the left ventricle are flaccid. The right ventricle contains a little fluid blood. Two small thickened patches of old endocarditis are at the base of the aortic valve. The heart muscle is firm and normal.

The *diaphragm* stands at the level of the sixth intercostal space on the left side, and at the sixth rib on the right side.

The *lungs* are non-adherent, pale, normal in size, texture, and consistence.

The *trachea*, *oesophagus*, and *aorta* are normal.

The *vocal cords* are in cadaveric position.

*Brain and Spinal Cord.*—The brain was removed in the ordinarily practiced method, and the scalp, pericranium, and skull show no effects of the head electrode. Skull brachycephalic.

Dura mater of convexity normal. Longitudinal sinus normal; contains a little fluid blood. Pia mater not thickened, but contains a number of nebulous striæ and opacities uniformly scattered over the whole convexity. There was considerable subpial fluid. Both this change in the pia mater and the increased subpial fluid are referable to some pre-existing condition, and are such as are not infrequently found in persons having the age and intemperate habits of this subject.

Convolutions of the brain have the normal topographical distribution; substance of brain normal, both as to the conditions of the blood-vessels and the character of both the gray and white matter. Vessels at base normal. Lateral ventricles contain a slight amount of clear fluid. Ependyma of all ventricles unchanged. Floor of fourth ventricle normal.

The right optic nerve—corresponding to the lost eye—is atrophied, having about half of its ordinary thickness. The medulla, pons, and basal ganglia show no abnormalities. (These were referred to Dr. Brill for microscopical examination.)

There is an old healed fracture extending across the right orbital process of the frontal bone, one centimetre from the median line, which extends backward and outward nearly to the apex of the petrous portion of the temporal bone for a distance of about five centimetres. The dura mater along the track of this old fracture is slightly thickened (to the extent of three millimetres) and adherent to the bone.

The superior portion of the *spinal cord* shows no changes in its coverings, vessels, or substance.

The muscles were critically examined to determine if there were any signs of violence induced by the current or the contraction it caused, and with a negative result. The muscles of the chest, abdomen, and calf were normal, bright red, firm, and show not the slightest tearing or rupture.

*Remarks.*—In looking carefully over the details of this autopsy and comparing this report with that of the four previous cases of infliction of the death penalty by electricity, the following points may be noted:

1. The passage of an electrical current of the pressure employed in these cases (of approximately from 1,400 to 1,700 volts) and in this manner does not do any damage to any of the internal organs, tissues, or muscles. None of these parts are lacerated or changed in volume; neither are there any gross chemical or morphological changes or alteration of their finer structural features.

2. The local thermic effects of the electrodes are limited to the outer scarf skin. The true skin beneath is not damaged to any appreciable extent. The epidermis or scarf skin may be separated from the deeper skin, and resembles in this way an ordinary blister from which the fluid has escaped. The blisters about the knee in this case are like the ordinary familiar water blisters on the hands from friction, or the blisters which physicians often have occasion to produce in their treatment of disease. Where the skin has been exposed to the weather, and is tougher and more resistant, as on the forehead and scalp, the blistering does not take place, whereas in the more sensitive delicate skin of unexposed surfaces, as at the fold of the knee joint or the calf, the superficial blistering is more readily induced. Compared with the four previous executions, the changes in the skin induced by the local thermic action of the electrode are even still less in degree in this case, and may be pronounced altogether trivial.

3. The occurrence and distribution of the minute hæmorrhagic spots (described more completely in the previous cases) are not a uniform or constant feature in these cases, and as they are found after death from the greatest variety of causes, they can not properly be regarded as positively characteristic of death by this method.

4. The attitude of the body on the autopsy table is peculiar and very uniform. When the electrodes are applied at the knee flexure, the leg is invariably slightly flexed at the knee and a trifle adducted.

*Charles McElraïne.*—Approximately two to three minutes after the breaking of the last current the reflex action of the voluntary muscles was tested as follows:

1. The patellar reflex was tried in the usual way without any response from the muscles either in the knee of the electrode side, which was rigid, or the knee of the other side, which was relaxed.

2. The cornea was touched with the finger without eliciting any exertion from the muscles of the eyelids.

3. The nipples were pinched with a forceps, and the surrounding skin was scratched and lightly scarified with fine scissors; but this did not induce any motion of the muscle groups, or even any fine fibrillary twitching of the individual fibers of the subjacent muscles.

4. One of the muscles of the abdomen (the rectus) was exposed, but showed no activity when cut or irritated with the knife. Voluntary muscle reflexes to ordinary stimuli were absent. The activity of smooth or involuntary muscle was *not* interfered with; thus peristalsis of the intestines and the cremasteric reflex could be excited.

After these tests the autopsy was made immediately.

I. *External Appearances of the Body.*—The subject is a trifle below the medium stature, well nourished, has no deformities, and has well-developed muscular system. The lips are pallid, but the nostrils and interior of the mouth are perfectly natural. The left eyelid is quite firmly closed, while the other lid is partly open. The delicate membrane coating the front of the cornea has not been disturbed by the head electrode. The pupils are about midway open, nearly uniform, and measure about two millimetres and a half in diameter. The eyeballs are natural. There is no distortion of the face, such as muscular contractions or marks of violence, to mar the countenance.

*Rigor mortis* is marked only where the current was applied; the electrode leg is flexed at the knee joint at an angle of about 90°, and is a trifle adducted. The arms, which received the first contact, are less flexed than the knee joint, and the fingers are almost completely closed in the palm of the hand.

There are no evidences of a seminal emission.

The skin is everywhere perfectly natural, except at the points of application of the electrodes, and here there are some superficial changes in the outer layers of the skin. In these places, at the back part of the right knee joint and on the upper surface of the wrists (where the first contact was made), the thin outer scarf skin is wrinkled and raised up or partially detached from the true or deeper skin beneath.

These superficial patches on the skin in the electrode regions are not extensive and do not measure more than two to two inches and a half in diameter. In order to see if these patches involved the skin beyond the outer layers, the whole skin was cut through with the knife and looked at critically. It was then seen that the deeper layers of the skin were but very little involved. The deeper or true skin is in places in these patches a little drier than it ought to be, and this is all. The layer of fat beneath the slightly superficially damaged patches on the skin is perfectly normal in every way.

II. *Examination of the Thoracic and Abdominal Organs.*—There is very little to be said about the examination of these organs other than that they were subjected to a thoroughly detailed systematic scrutiny, and nothing abnormal was found either about their shape, consistency, or texture, except the left ventricle of the heart was firmly contracted, while the right ventricle was flaccid. Valves and heart muscle normal.

The left kidney (measuring 6 × 13 centimetres in diameter) contained a number of larger and smaller cavities (the largest one centimetre and a half in diameter) near the region of the pelvis, some of which contain calculi. Such a condition of the kidney is due to an old chronic previous process, and is to be expected in persons who develop calculi in the kidney.

All of the viscera and organs of the thorax and abdomen were examined.

III. *The Central Nervous System.*—The brain is brachycephalic and is perfectly normal as to its coverings, in the disposition and structure of its blood-vessels, in the arrangement of the convolutions, fissures, and sulci, and in the texture and relative distribution of the gray and white matter. The fourth ventricle and its floor are normal. The superior portion of the spinal cord is normal. (The brain was not completely dissected, in order that it might be transported to Professor Donaldson, of Clarke University.) The brain with the pia weighed, on scales weighing to half a gramme, 1,442 grammes. The dura mater weighed 52 grammes.

IV. *The Muscular System.*—The muscles are red and firm and show no signs of tearing, rupture, or hæmorrhage.

*Conclusion.*—As might naturally have been expected, the adoption and successful inauguration of this new method of capital punishment has not been accomplished without encountering vigorous opposition, amounting in some instances to violent and apparently malicious denunciation of the acts and motives of those who were called upon to act as principals in carrying out a law the establishment of which must eventually be regarded as an important advance in criminal jurisprudence in the direction of a higher civilization. But even to-day, despite the wide publication of unofficial reports, proclaiming the method a failure and apparently designed to invest it with an air of repulsion, brutality, and horror, it is conceded by substantially all unprejudiced individuals who have witnessed these executions, or who are reliably informed as to the facts relating thereto, as well as by a large and increasing proportion of the daily press, that the intent of the law to effect sudden and painless death has been fully attained in each instance. That a method of judicially inflicting the penalty of death in punishment of the crime of murder will ever be devised which in its operation shall be divested of that sense of awe and dread usually experienced, especially by laymen, when in the presence of death, is not to be expected; and even were it possible, the wisdom of such a method might well be questioned, so long as the welfare and protection of society require the infliction of such a penalty to deter men from committing murder.

It should be borne in mind that up to the time of Kemmler's execution there was no recorded instance of death having been deliberately effected on the human subject by this method, the only knowledge on the subject being derived from experiments on lower animals and from observations in cases of death from accidental contact with live electric wires and from such deductions as could logically be made from technical knowledge of electro-motive force; hence the first execution by electricity was necessarily to some extent experimental and attended with possible elements of uncertainty, owing in part to crudeness in the law and in part to certain minor defects in the arrangement and operation of the apparatus and to the inexperience

of those in charge. In spite of these defects, however, the important fact remains that the prisoner was instantly rendered unconscious and death was painless.

Of the nearly one hundred physicians, many of whom are eminent members of their profession, who have witnessed one or more of these executions, only two have dissented in any essential particular from the conclusion that this mode of inflicting the death penalty destroys conscious and organic life, both aggregate and segregate, with a suddenness and thoroughness that is not attained by any other known method. One of these gentlemen, a distinguished surgeon and an ardent opponent of capital punishment in any form, witnessed the Kemmler execution, and while concurring in the general opinion that unconsciousness was instantly produced by the first contact, still thought there was a possibility that resuscitation might have been accomplished by means of hypodermic injections of brandy—that is, after the first contact. The other dissenting physician, who is an advocate of the execution of criminals by means of suffocation with toxic gases, witnessed the execution of McElvaine. He also agreed that unconsciousness was instantly produced by the first contact, but thought that the second shock was required to effect absolute death. There is no reason to doubt the sincerity of either of these gentlemen.

Dr. Van Gieson, in his official report of the McElvaine autopsy, in speaking of the rapid abolition of reflex action of the voluntary muscles, says:

This tends to show how superlatively complete and far-reaching the effects of the currents are in abolishing life, not only in the concrete form, but also in the integral activities of the body which in other forms of sudden and violent death is liable to persist for a time after life is extinct. From observations at this execution, as well as at the subsequent examination of the body, the current appears at first not only to extinguish life in the ordinary sense of the word, so far as consciousness, feeling, and volition are concerned, with overwhelming suddenness, but reaches beyond this and destroys the energies of the individual component parts of the body so that they can not be raised into activity by artificial mechanical stimulation, as is usually the case in sudden violent death.

The experience thus far had has demonstrated that the only reasonable objection to so-called "electrocution"—at least so far as the individual is concerned—as compared with other modes of inflicting the death penalty, lies in the fact that the application of a current of lethal energy results in the generation of heat at the point of contact, and, if sufficiently prolonged, is attended with vesication of the skin at that point, owing to the temperature of the moisture on the electrodes becoming elevated to the boiling point, while if the sponges are allowed to dry out, local burning may occur. This occurs, however, if at all, toward the end of the contact and long, comparatively, after conscious life is extinct; hence the objection is, after all, merely a sentimental one. Furthermore, it may reasonably be assumed that a method of avoiding this local thermal effect will soon be determined.

Finally, as compared with hanging, in which death is frequently produced by strangulation, with every indication of conscious suffering for an appreciable time on the part

of the victim, execution by electricity is infinitely preferable, both as regards the suddenness with which death is effected and the expedition with which all the immediate preliminary details may be arranged. By the latter method the fatal stroke renders the subject unconscious in an infinitesimal fraction of a second—so small as to be beyond the power of the human mind to estimate it—while, at the same time, it destroys both conscious and organic life in a shorter space of time than is possible by any other known method. In other words, it is the surest, quickest, most efficient, and least painful method of inflicting the death penalty that has yet been devised.

334 FIFTH AVENUE.

## ELECTRICAL EXECUTION.\*

By W. J. JENKS.

PROFESSOR LAUDY has expressed the feeling which I experienced regarding the possibility of accidental interruption of the current at a critical moment during an electrical execution, and I think it important that any such possibility should be guarded against as further experience may dictate, principally in two ways—first, by making the apparatus, engine, belting, dynamo, and circuit of ample capacity, and partially loading it by operating a considerable number of lamps or otherwise, so that when the sudden strain is put upon it by the completion of the circuit through the body, the additional load may be a small percentage of the total output at that moment or of the total capacity; second, by reducing, as far as is feasible, the energy applied.

Dr. Morton's remarks have very greatly instructed and interested me. If he will permit me, however, I should like to call the attention of the gentlemen present to a few considerations and a few methods of expression which may point the way to a clearer appreciation of just what occurs to the body of the man upon whom the hand of justice is laid in the application of the extreme penalty which human power can inflict, in the form of instantaneous electrical death.

Dr. Morton has to-night truly said that it is not the mere voltage that kills. Perhaps a desirable form of expression is that it is the expenditure of that voltage at a certain rate for a certain time.

But the indefinite ideas that prevail on this subject are well illustrated by an incident which is a matter of public record. Not long ago a gentleman who has a wide reputation as an instructor and a man of science made some remarks on this point in testimony before the Board of Aldermen of the city of Boston. In the course of his examination the following record was made by the stenographer:

"Q. Now, when such a current (alternating) is applied to the human body, it has a tendency to disintegrate all of the tissues of the human body, and is necessarily fatal?"

"A. It depends on how much there is of it. I have taken alternating currents, and every one knows that they are used in connection with medical treatment.

"Q. What voltage?"

"A. Oh, millions of volts. I have taken the current from an ordinary little medical machine—well, I will be very conservative and say, to the extent of half a million volts.

"Q. But a small quantity of electricity?"

"A. Small in quantity; yes, sir.

"Q. It would be like taking a stream of water so small that you could hardly see it, and projecting it with great force?"

"A. It would be projecting it backward and forward; it is really vibration."

Now, while at a first reading of these expressions they may appear to agree with Dr. Morton's proposition, it is difficult to imagine more misleading statements. If there is any medical electrical machine in existence that will resist the pressure of 500,000 volts tending to break down its insulation, the fact that it could produce that electro-motive force would by no means prove that any such pressure was expended in the body of a person who might use it. It does not require much power to produce a difference of potential of 500,000 volts, but it would require an enormous power to *maintain* that pressure if given an opportunity to expend itself in a human body, for, assuming a resistance of 200 ohms, we should find a fall of potential of 2,500 volts for every ohm, or, as we usually express it, a current of 2,500 ampères.

To apply a pressure of 1,000 volts, alternating from two hundred to three hundred times a second, and *maintain* that pressure for an appreciable time against the resistance of the human body, does not probably greatly increase that resistance at the instant of contact. Or, if it has such an effect, the *maintenance* of the so-called current reduces the effective resistance so speedily that we get the expenditure, from 1,000 volts (to say nothing of 500,000 volts), of such tremendous energy as snuffs out the life of the criminal more quickly, as the graphic language of Dr. MacDonald's paper has explained, than neural impression can be carried from the point of contact to the seat of sensation in the brain.

The energy that kills is therefore the product of three factors—(1) the electrical pressure or electro-motive force that is applied to the surfaces of the body, or, in more accurate technical language, the effective difference of potential (in volts) between the electrodes, shown by the Cardew voltmeter; (2) the rate of expenditure of this potential in each unit of resistance in the body, or the number of volts fall of potential to the ohm (ampères) shown by the ammeter; (3) the time (seconds) shown by the stop-watch. The volt-ampères (watts) give the rate at which the work of destruction is going on; the volt-ampère-seconds (joules) are the measure of energy expended or heat developed in the body during the time of contact.

None of these factors are well settled as yet in their relation to the energy actually required to cause instant and painless death. By "death" I mean now, not alone cessation of consciousness of a perfectly healthy human being in an interval too brief for thought to measure, and the establishment of conditions which produce gradual and final expenditure of the stored nervous energy of the brain and the subordinate centers of distribution of vital force—such as the pneumogastric nerve and the spinal column—I mean,

MR. JENKS'S ARTICLE ON ELECTRICAL EXECUTION.

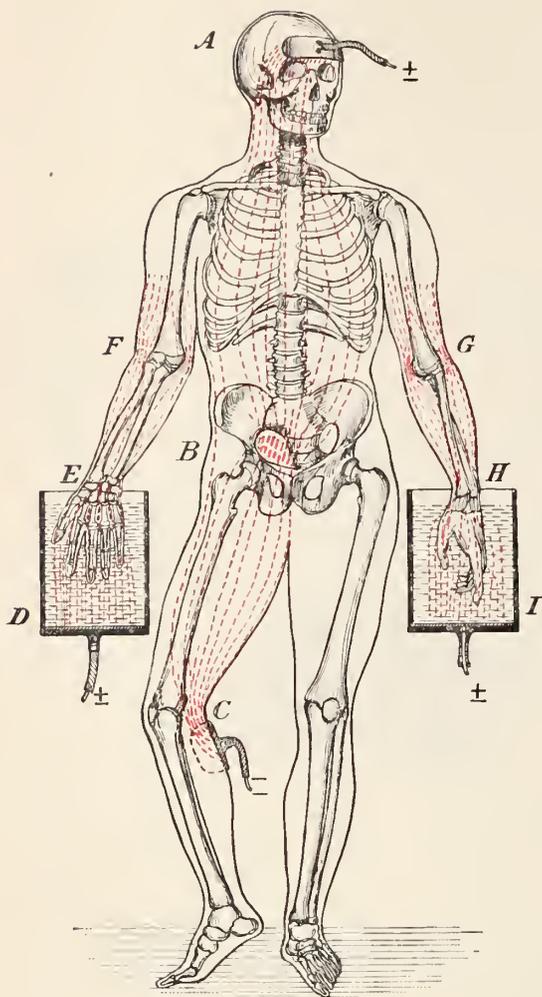

FIG. 1.

FIGURE 1.

Assumed distribution of resistance, and expenditure of energy which would result from such distribution, illustrative of possible conditions of second contact in McElvaine's electrocution. Total potential, 1,500 volts; average current, 7 ampères. Total resistance indicated by volt and ampère readings, 215 ohms. Width of channel through the body illustrates assumed comparative conductivity. Total watts expended  $(1,500 \times 7) = 10,500 = 14$  H. P. Only

$\frac{490}{10,500} = 4\frac{2}{3}$  per cent. of total energy is by this assumption expended upon the large channels of blood, the heart and lungs, and the nerves between the neck and hips.

C.—Surface contact and adjacent tissues say within six inches of electrode on the leg: 80 ohms, 560 volts drop, 3,920 watts.

C to B.—Knee to trunk: 45 ohms, 315 volts drop, 2,205 watts.

B to A.—Heart and trunk generally: 10 ohms, 70 volts drop, 490 watts.

A.—Surface contact of head electrode and adjacent tissues: 80 ohms, 560 volts drop, 3,920 watts.

FIGURE 2.

Assumed distribution of resistance and expenditure of energy illustrative of possible conditions of first contact in McElvaine's electrocution. Total potential, 1,600 volts; average current, 2.5 ampères. Total resistance, 640 ohms. Width of channel through body illustrates comparative conductivity. Total watts expended  $(1,600 \times 2.5) = 4,000 = 5\frac{1}{3}$  H. P. Only  $\frac{135}{4,000} = \frac{1}{32} = 3$  per cent. of

total energy is here expended upon the large channels of blood and the nerves between the shoulders and the heart and lungs.

D to E.—Heart and trunk generally: 20 ohms, 50 volts drop, 125 watts.

C to D.—Elbow to shoulder: 50 ohms, 125 volts drop, 312 watts.

B to C.—Wrist to elbow: 250 ohms, 625 volts drop, 1,562 watts.

A.—Salt-water contact: 10 ohms, 25 volts drop, 62 watts.

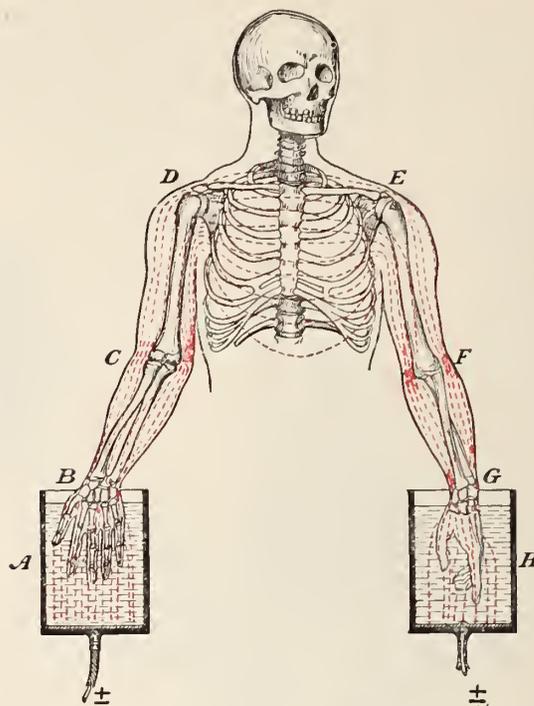

FIG. 2.

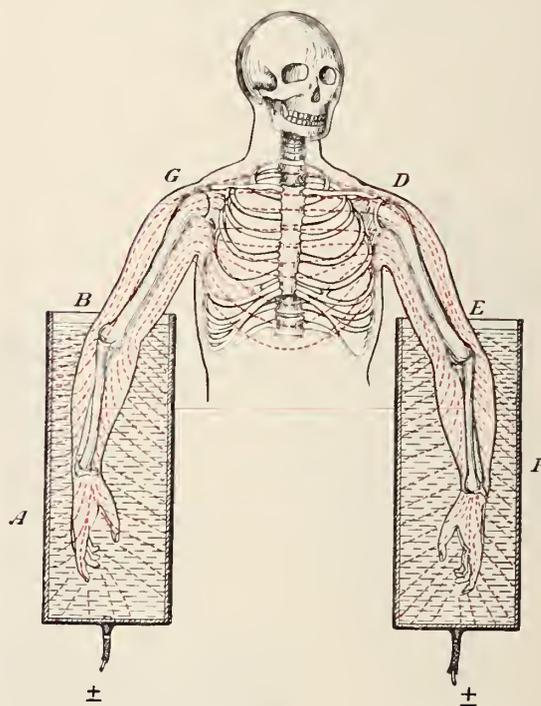

FIG. 3.

FIGURE 3.

Assumed distribution of resistance and expenditure of energy illustrative of possible conditions of a contact from arm to arm, immersed to the elbow, the total potential remaining as before, but the current, of course, increasing and the distribution of fall of potential entirely changed. Width of channel illustrates comparative conductivity; current, 11.43 ampères. Total resistance, 140 ohms. Total watts expended  $(1,600 \times 11.43) = 18,288$  watts, or  $24\frac{1}{2}$  H. P.  $\frac{2,613}{18,288} = 14$  per cent. of total energy is here expended upon the blood channels, nerves, and lungs.

A.—Salt-water contact: (say) 10 ohms, 114 volts drop, 1,303 watts.

B to G.—Elbow to shoulder: 50 ohms, 571 volts drop, 6,532 watts.

G to D.—Heart and trunk generally: 20 ohms, 228 volts drop, 2,613 watts.

also, total paralysis of all the vital organs and of the nervous centers by which they are directly or indirectly vitalized, and by which the muscles of the extremities are actuated, so that when the current is broken there can be no reflex action of the muscles, such as would indicate the presence of residual life energy, or a possibility of its resuscitation.

I think none of these factors are settled, because it is not yet known how small a resistance may be found when only those parts of the body which must be paralyzed, and the surface tissues which most readily lead the current to those parts, are included in the circuit. That the contact surfaces are excellent (and satisfactory) no intelligent witness of one of the later executions will deny. The peculiar scalding effects of the current at the edges of each of the electrodes nearest to the electrode of opposite polarity, and for some distance along the track most readily followed by the greatest density of the current, has been attributed—erroneously, I think—to the contacts themselves, and to the idea that accidental surface moisture has been followed by the current and heated till dissipated in vapor.

The rough sketch (Fig. 1) will illustrate what I believe to be the correct idea. Near each electrode the area of comparatively good conducting material (moisture-filled tissues) which lies in the line of least resistance is limited, and a high degree of current density results, until in its course from one electrode toward the other the current finds an expanded path and can spread itself over a larger area without departing very much from a direct line, or at any rate without encountering largely increased resistance. Within this area of great current density or large expenditure of volts to the unit of cross-section of the conducting tissues the few blood-vessels, nerve channels, and moisture ducts oppose so great a resistance to the rush of energy as to occasion a great drop of potential and thus great heat, and the moisture is quickly raised in temperature to the scalding point. Much of it must have been turned to steam under the epidermis and perhaps in the minute blood-vessels, and those portions of the body close to the electrodes are parboiled if a large current is maintained.

How useless this great expenditure of potential is, I have tried to show by the calculations attached to Figs. 1, 2, and 3. The correctness of this general analysis was demonstrated by the intensity of the heat observed in the fore-arms and near the head and leg electrodes in the case of McElvaine, and the fact that the bony structure of these parts of the body contributed materially to the resistance was evident from the high temperature (120° F. or more) which was noted for nearly two hours after death.

It is also evident that a fall of potential, under the conditions of Fig. 2, between the hands and the shoulders is not useful in producing instant death. Hence it appears that the energy expended outside the vital centers (on the assumptions of these rough sketches) is greater by far than that which actually accomplishes the paralysis desired. Hence, probably three quarters or more of the total horsepower applied to the body is of no substantial effect. If a current of the same number of ampères could be expended exclusively at the life centers, it might be found that only

a low voltage (perhaps 100) would be ample, and that the concentration of 10 ampères or less in these centers of nervous activity might allow of the reduction of the time also to a fraction of what has thus far been considered necessary or desirable.

For example, in the case of McElvaine, the heat energy expended was approximately, in the first contact, 1,600 (volts)  $\times$  2.5 (ampères)  $\times$  50 (seconds) = 200,000 (joules); in the second contact, 1,500  $\times$  7  $\times$  36 = 378,000; total, 578,000 joules.

Suppose it should be found that proper application of the electrodes would reduce the voltage to 200, the ampères to 5, and the time to 10 seconds. We should then have an expenditure of only 10,000 joules of energy, and may it not be found in the future practice of this method that thus no disfigurement of the body need be produced, and absolute animal death may occur more quickly than that of any of the seven victims of whom Dr. MacDonald has spoken? Thus the "forty-horse-power death" desired by Dr. Morton may not be necessary. May it not often be the case that death by the thunderbolt is caused by the expenditure in the body of 10,000 volt-ampères or even less for  $\frac{1}{100000}$  of a second, or even a shorter time?

As an aid to a settlement of these questions of how many volts, ampères, and seconds are necessary, or rather how few of each can be relied upon to do the work with absolute certainty, it would be important to determine the relative resistance of various portions of the body, because when we apply a deadly current, the fall of potential and the work done at every point are in exact proportion to the percentage which the resistance of that point bears to the resistance of the whole.

I regret that Mr. A. E. Kennelly, consulting electrician at the Edison Laboratory, with whom I attended McElvaine's execution, is not present. In his absence I will take the liberty to read extracts bearing upon this point from a letter which he wrote me under date of March 14th, in answer to the suggestion I have just expressed.

"I think that a high pressure brought to bear upon a man's body between any two points, say hand to hand, finds the resistance initially just what we measure it by the bridge, but that it breaks down at a rate rather difficult to foresee. Also that valuable experimental measurements could be made (as you suggest) of the resistance in different parts of a man's body, thus—[drawing] "A B represents (diagrammatically, I should mention) a man lying on his back in a semi-nude condition. A battery or dynamo current (direct or alternating) is applied of the right and readily supported strength at convenient points, say the extremities C and D, by means of wet bandages. Sponge-faced electrodes E, F, connected with an electrometer, are then moved from point to point by various distances apart and the fall of potential studied. I suspect—without pretending to know—that the resistance of the body and its distribution from point to point mapped out by this method, would be maintained in ratio or relative proportion under fatal pressures, even though the absolute resistance fell everywhere.

"I confess that, while the hand method is the simple and practical method with or without deep immersion as you outline it, the head method is the true way for rapid and complete nerve destruction. I give that point to the doctors. I do not think that the difference between three and seven ampères ac-

counts for the difference we saw in the after-effects and reflex sensibilities.

"I think that an accurate knowledge of the resistance from point to point of an average human body might assist occasionally in the diagnosis of disease, and the comparison with the resistances of a corpse might have useful results to show."

I am not a believer in capital punishment. The idea is to me revolting and inconsistent with the theory of a high civilization. It has never seemed to me that the deliberate destruction of human life ought to be necessary to the well-being of society. The same safety might, I think, be secured by a law which would doom the murderer to life imprisonment beyond any possibility of escape save the one chance of proving that he had been wrongfully convicted.

But if "life for life" is in the future to be the law of the land, electricity is an agent by which we may take life swiftly, surely, and mercifully. The dignity which has marked the electrical executions thus far has been as noteworthy as the previously unattained rapidity of every movement by which the result has been secured.

## INFLUENZA IN NORTHERN NEW ENGLAND.

BY S. B. OVERLOCK, M. D.,

STEBEN, MAINE.

As to the articles that have been written on *la grippe* since it has become a prevalent epidemic disease in this country their names are legion, and my only excuse for offering anything additional to the medical profession is that my experience with the disease has been confined to a section of country different from that of any author's whose article has come to my notice. Also, that while the mortality has been high in towns but a few miles distant from this, out of over three hundred cases to date no one of them has ended fatally here.

The outbreak of this disease during the present winter has been more severe than that of last winter or of two years ago, a much larger number of cases terminating in pneumonia. During the latter part of December and the whole of January the epidemic was confined to the outlying districts east of the town and along the sea-board, not a single case appearing in the town proper, or in the outlying farming and lumbering sections to the westward. After nearly every person, and at times whole families, had been prostrated and recovered in the first-mentioned sections, cases began to appear in town, which rapidly spread into the outlying districts westward. Every age and condition were alike seized—hardy fishermen and lumbermen, exposed to every change in weather, and the merchant and artisan, who had hardly been out of doors for the winter—showing conclusively that "colds" had little or nothing to do with the spread of the disease.

Clinical features have varied according to age and physical condition of the patient, but all have had enough in common to furnish a chain of symptoms highly characteristic of the disease. In children under ten or twelve years of age vomiting has been an almost constant symptom.

Constipation has prevailed in a large majority of cases; in a few the reverse has been present—diarrhœa. In adults rapidity of pulse, marked rise in temperature, cephalalgia, and pain in limbs have been constant symptoms for the first twenty-four hours. At the end of this time a cough and acute bronchitis are prominent features. In aged people there is always a sense of fatigue, nervous depression, and sometimes somnolence.

In the epidemic of two years ago an attempt was made to formulate some regular plan of treatment, but without satisfactory results. In the present epidemic a general plan of treatment has been followed, varying, of course, with the age and general physical condition of different patients. In sthenic subjects with high arterial tension, marked rise of temperature, cephalalgia, pain in limbs, if there has been no movement of the bowels for the previous twenty-four hours or longer, a full dose of calomel was usually given, and if this failed to produce an evacuation in twelve hours, it was followed by a saline. In one hour ten grains sulphate of quinine with Dover's powder was given. In a short time the skin became moist, arterial tension began to lower, cephalalgia and pain in the limbs to abate. Tincture of aconite in small doses frequently repeated was given, watching meanwhile respiratory movements. The aconite seemed to lessen the amount of work done by the organs of respiration, and by blunting sensibility of the sensory nerves relieves the neuralgic pains to a greater extent than any other antipyretic. Usually after twenty-four hours' treatment arterial tension has become nearly normal, temperature is reduced in a marked degree, and there is little or no pain in head or limbs. When bronchitis was present, as it may be said to have been in every case, an expectorant mixture consisting of fluid extract of ipecac, chloroform, and syrup of squill or Tolu syrup was given every two, three, or four hours, according to indications. If the expectorated matter was particularly viscid or took on the peculiarly bluish tint seen in many instances, carbonate of ammonium and iodide of potassium or iodide of ammonium was added to the cough mixture. If a marked sore throat was present, chlorate of potassium was used with good results, combined either with the expectorant mixture or with tincture of the chloride of iron, and applied to the throat with a swab. Pneumonia, as a complication, received the usual treatment. Alcoholic support was used earlier than in a pneumonia not preceded by *la grippe*. With children the principal antipyretic used was the liquor ammonii acetatis. This with a simple cough mixture usually brought the attack under full control in from eighteen to twenty-four hours. In old and feeble subjects alcoholic stimulants and an expectorant were administered at once, and this was the principal treatment adopted.

In a few cases the newer analgesic, antikanina, was used with good results, so far as relief of pain was concerned. Acetanilide and antipyrine do not fulfill the indications or meet the wants of the patient in the symptomatic fever accompanying the disease. Physicians who use acetanilide, especially in case of the weak, irritable heart of brain-workers, will be obliged to write "heart failure" frequently in their death certificates.

THE  
NEW YORK MEDICAL JOURNAL,

*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, MAY 14, 1892.

THE THYREOID GLAND AS A CAUSATIVE AND CURATIVE  
AGENT IN MYXÆDEMA.

In an interesting paper on the function of the thyreoid gland, published in the *British Medical Journal* for January 30th and February 6th, Mr. Victor Horsley concludes that this gland, is a structure essentially connected with the metabolism of the blood and tissues, being both directly and indirectly hæmatopoietic in fulfillment of its functions, secreting from the blood a colloidal substance that is transmitted by means of the lymphatics from the acini of the gland to the circulation. This position seems to be sustained by the general results of experimental thyreoidectomy, and they seem also to favor the view that the gland is an important origin of metabolic influence. As a consequence of experimental researches, he believes that the symptoms of disease or obliteration of the gland may be divided into a first, or neurotic; a second, or myxædematous; and a third, or cretinic stage. Death may occur in any of these stages, according to the virulence of the cachexia. The indispensability of the gland seems to be demonstrated by the hypertrophy of its tissue when a portion of it is lost; and a certain proportion of its tissue must be maintained for the purpose of health, though its importance varies with the activity of the vital processes, being greatest in early life and diminishing with age.

The constant additions that experimental physiology has made to our knowledge of the functions of this gland have been a stimulus to further research regarding the means of alleviating the conditions consequent upon its disease or removal. Among the first experiments were those made in grafting a portion of an animal's thyreoid into the peritoneal cavity or on to some other structure of an individual afflicted with the "cachexia strumipriva." But such an operation is open to many objections.

Recently experiment and practice have essayed another method. Mr. George Murray presented a paper at the last meeting of the British Medical Association (*British Medical Journal*, Oct. 10, 1891) in which he stated that, if we considered that myxædema and cachexia strumipriva were due to the absence from the body of some substance which was present in the normal thyreoid gland, and which was necessary to maintain the body in health, it was at least rational treatment to supply that deficiency as far as possible by injecting the extract of a healthy gland. Vessale's experiments with intravenous injections of an extract of that gland in dogs after thyreoidectomy suggested the beneficial results that would follow similar injections, and in his paper the author reported the case of a lady, aged forty-six, who had suffered with myxædema for five

years, in which sterilized extract of sheep's thyreoid was injected hypodermically with resulting improvement in all the symptoms of the disease.

Recently Dr. W. Beatty (*British Medical Journal*, March 12, 1892) has reported a case of this disease in a lady, aged forty-five, who had had gradually progressive symptoms for four years, in which he first tried massage for five weeks with very moderate benefit. Then injections of the extract of sheep's thyreoid were given at intervals of from four to ten days with rapid and marked improvement in the patient's condition.

In a communication to the same journal for October 10, 1891, Mr. E. Hurry Fenwick reported a case of myxædema in which he had grafted a sheep's thyreoid, and on the following day the temperature had risen from its usual subnormal level to normal, while the urinary excretion increased from twenty to fifty ounces per diem. In a subsequent case of the disease in which he injected thyreoid juice hypodermically similar results were obtained, persisting for twenty-one days and occurring more rapidly. So it seems from this latter report that the action of the juice when injected is quite rapid and, as compared with the operation, quite as efficacious.

It has not yet been demonstrated that the thyreoid tissue will persist as such after transplantation, and, while the beneficial results of injections of the juice may be limited to the time during which their use is continued, still the excellent results obtained in an amelioration of the symptoms of what has been considered an incurable disease would warrant their administration with the precautions the originator has prescribed.

A MUSICAL ANUS.

SOME four or five years ago M. Verneuil exhibited to his class in Paris a case of what he facetiously denominated "musical anus." The patient was able at times, when sufficient flatus had accumulated in his colon, to evacuate it with some force, thereby producing a high-pitched musical note resembling that of a violin. On close examination, he was found to have, in the cellular tissue about the lower end of the rectum, a pneumatocele, with an opening into it from the rectum, formed by a narrow slit between two thin folds of mucous membrane, which, acting like a reed, produced the sound when the air was expelled from the tumor by forcible pressure from above. Numerous cases of fistula and other deformities of the anus have been seen in which the expulsion of gas from the bowel was accompanied by peculiar sounds, some perhaps musical to the enthusiastic observers. But in all these cases there has been some deformity or malformation of the rectum or anus.

Dr. Baudouin, however, has lately reported in the *Semaine médicale* a case that may with justice be called one of musical anus, and one that is of much interest from a physiological point of view. The patient, or rather the exhibitor, is a man aged thirty, well developed, but without muscular excesses, tall, of full weight, and, so far as can be made out, entirely free from any disease or deformity. His digestion is good and he does not develop an unusual quantity of gas in the bowel after

eating. There is no pyrosis or abdominal tympanites. His fæcal passages are normal, regular, and well molded. The anus and rectum, in a state of repose, present nothing abnormal. The sphincter is moderately strong, but quite distensible, notwithstanding its daily exercise. The rectum is normal and not dilated. The remarkable feature of the case is that the lower bowel, at least, seems to be absolutely under the control of the man's will. He can empty it completely whenever he desires, a very fortunate accomplishment for his clothing and for the olfactories of his audiences. He was reared on the shores of the Mediterranean, and it was here that he first noticed his remarkable power. While bathing one day he observed upon strong inspiration the sensation of cold in his pelvis and abdomen, and at the same time felt the sea water entering his rectum. In a short time he was compelled to empty his bowel, and noticed that he had taken in a much larger quantity than he had supposed. By practice in the ordinary bath and in the sea, he became able to store a considerable quantity of water, to retain it for some time, and to eject it with much greater force than at first. Later on he noticed that he could accumulate air in his bowel, as well as water, and by its expulsion could give rise to certain variations of sound. Applauded by his associates, who acknowledged his superiority in this class of exercise, he eventually developed the faculty beyond measure, and frequently gave exhibitions of his art before a select circle of his friends. From these reunions he began to exhibit his powers in the clubs and cafés until he became the best-known and greatest curiosity of the place. As his reputation spread he made journeys to the surrounding towns and villages, Bezin, Nîmes, Toulouse, and Bordeaux. At the latter place he was examined by many of the medical faculty, and a discussion of the case was reported in the *Gazette hebdomadaire des sciences médicales de Bordeaux* for March, 1892, in which Dr. Ferron and Dr. Boursier said they had each seen men possessing the power of storing and expelling considerable quantities of water from the rectum, but had never seen one able to draw in and expel air. In addition to this power, however, this individual has a peculiar control over the external sphincter, by which he is able not only to control the escape of air but also to imitate the sounds of a violin, a trombone, and other instruments, and to reproduce melodies thereby which may be distinctly recognized. To do this he stands with his legs straight, his body flexed upon his thighs, and his head bent first to one side and then to the other. During the performance he moves his buttocks in all directions, seeming thus in some way to be able to govern the conformation of the anus and to produce the different sounds and tones. There is said to be no disagreeable odor to the expelled air, as he clears the ground well before beginning operations. The process consists of two acts, inspiration and expiration, the former taking only one or two seconds, and the latter being capable of being prolonged from ten to fifteen seconds.

These facts have been verified by Professor Richet and Professor Poirier, who have made a prolonged study of the case, as well as by many others of the faculty of Paris. From a

physiological point of view the case is very interesting, opening up the field for discussion and study as to how far the colon can be made to supplant or supplement the lung in voluntary respiration, and the sphincter of the anus to take the place of the lips in playing on wind instruments.

## MINOR PARAGRAPHS.

### ALBUMOSURIA.

DR. LEE DICKINSON, as reported in the *Medical Press and Circular* for December 2, 1891, has presented before the Clinical Society of London twenty cases of pneumonia and other affections in which the urine contained albumose. These cases, or some of them, are probably the same essentially as those that have in times past been designated peptonuria. Neither by Dr. Dickinson nor by Dr. Fyffe, his collaborator, was true peptone found, but whenever the biuret, or purplish-red, reaction was obtained, albumose was its cause. This is a point of importance because many albumoses are poisonous, and the ordinary albumoses of peptic digestion have a much more powerful action than true peptones when injected into the circulation of animals. From the effects of injections in animals it seems probable that the diarrhœal complications from which many of these patients suffered may have been due to the passage of albumose through their blood. The noteworthy point in these cases was their high mortality; they also were marked by serious sequelæ, apart from the development of empyema. Again, it was noted that albumosuria was absent throughout some of the cases that were accompanied by extensive hepatization of lung and had a virulent course and fatal termination; and it is judged probable that, *ceteris paribus*, a favorable prognostic sign in severe pneumonia may be based on the existence of albumosuria. The origin of the albumose is pus, or at least inflammatory exudation, especially that of pneumonia; and it is probable that it is the product of the pyogenic micro-organisms. Albumosuria has been observed in acute rheumatism. Ovarian cysts when ruptured have been recognized by the presence of albumose in the urine. This substance is clinically related with intercurrent diarrhœas, but it seems to have no special relation with organic renal disease.

### PHYSICAL INSTRUCTION IN THE PUBLIC SCHOOLS.

THE superintendent of the public schools has prepared a scheme of instructions in physical exercise, to be the guide of the principals of the various schools in teaching gymnastics to their pupils. At present there is more or less of drill in calisthenics in most of the schools, but there are special appliances in five schools only. Next year the number in which appliances will have been introduced will probably be quadrupled. A regularly educated physician has been appointed to have oversight of the physical instruction in the schools, under the control of the Board of Education.

### THE RED BLOOD-CORPUSCLES AS A SOURCE OF ANIMAL HEAT.

THE *Lancet's* Paris correspondent states that Professor Mosso, of Turin, has recently communicated to the *Société de biologie* an account of certain experiments of his going to show that the red blood-corpuscles have something to do with the thermogenic function. Having curarized a dog, Professor Mosso practiced artificial respiration with hydrogen, so as to remove every trace of carbon dioxide. Sensitive thermometers were then inserted,

one into the carotid artery, and others into various viscera; whereupon, as soon as artificial respiration with ordinary air had been begun, the mercury in the carotid thermometer suddenly rose, while in the others it did not.

#### THE NEW YORK EYE AND EAR INFIRMARY.

THE family of the late Dr. Abram Dubois, who for many years was one of the surgeons of the infirmary, are, it is announced, about to add to it a pavilion in his memory. As this will require the destruction of a portion of the old building and the erection of another new one, the trustees will appeal to the public for contributions to the necessary fund. These they ought to have no difficulty in obtaining to any requisite extent, for the institution has served the community most solidly for well-nigh three quarters of a century, and has been remarkably well managed.

#### THE "KAISERQUELLE" AT TÖLZ.

THE *Medical Press and Circular* for January 20th comments on an apparently intentional deception in the matter of an alleged mineral water. The Kaiserquelle spring has been lauded as the richest "iodine spring" in the world since the time of its so-called discovery in 1890. It has been shown in a court of law that it was a manufactured and not a natural product. The "discoverer" of the spring, named Bertsch, caused a small stream of water to pass through a milk-can filled with a lot of chemicals suitable to yield the kind of water he thought he could sell to sick people. All might have gone well if the owner of the spring could have kept his secret a year or two longer.

#### FEVER AT FLORIDA RESORTS.

SOME of our citizens are said to have made a speedy exodus from Florida recently, under the belief that a fever, typhoidal in nature, had appeared at two or more of the best hotels frequented by Northern people. There have been some serious cases of sickness brought home from the South, but no deaths have been reported.

#### ITEMS, ETC.

**The American Surgical Association** will meet in Boston, in the hall of the Natural History Society, on Berkeley Street, on Tuesday, Wednesday, and Thursday, May 31st and June 1st and 2d, under the presidency of Dr. Phineas S. Connor. The preliminary programme gives the following titles: The Treatment of Uncomplicated Fractures of the Lower End of the Humerus and of the Base of the Radius, by Dr. John B. Roberts, of Philadelphia; Fibroid Tumors of the Uterus, by Dr. John Homans, of Boston; Surgical Operations on Persons suffering from Diseases not connected with that necessitating the Operation, such as Chronic Malarial Poisoning, Diabetes, Organic Heart Disease, etc., by Dr. W. T. Briggs, of Nashville, Tenn.; The Surgery of the Tongue, by Dr. N. P. Dandridge, of Cincinnati; Conditions demanding Excision of the Globe of the Eye, by Dr. W. H. Carmalt, of New Haven, Conn.; Ancient Contractures of the Hip and Knee Joints, by Dr. T. F. Prewitt, of St. Louis; and A Report of Operations upon Spina Bifida and Encephalocoele, with remarks, by Dr. A. T. Cabot, of Boston.

**The Death of Dr. Charles Fremont Clark, of Brooklyn**, occurred on April 21st. He was born at Wheeling, West Virginia, in 1856. He obtained his education in letters at the Washington and Jefferson College, and was there graduated in 1878. The College of Physicians and Surgeons gave him his medical degree in 1883. After a year spent as interne at the Brooklyn City Hospital, he was for several years in private practice in Brooklyn. His final illness was apparently of the nature of an obscure typho-malarial fever. He had for seven or eight years past supposed himself to be the victim of malarial poisoning, and

he had treated himself for that condition until about a week before his death. He then had alarming elevations of temperature, as high as 107° F., also a great increase of abdominal pain. Consultations were called, but the unusual elements of Dr. Clark's malady could not be satisfactorily accounted for, and its untoward progress could not be stayed. An autopsy revealed the true cause of this painful attack and untimely death to have been a chronic inflammation of the vermiform appendix, on which an acute attack had supervened, with multiple metastatic supuration in liver, lungs, and kidneys. He was found also to have been the subject of an abnormally free, or "floating," caput oeli. The mesentery on the right side was faultily developed and permitted the caecum and appendix to swing out to the left side in such a way as to keep alive and to aggravate the trouble that had probably begun years before in the appendix. The latter organ contained a foreign body, which had evidently been the source of a chronic and sub-acute irritation, and given rise to the belief that malarial influences were at work to undermine the sufferer's health. Dr. Clark's life appeared not to have been in imminent peril, except for the added burden of this anatomical abnormality, the floating caecum, which masked the ordinary indications for surgical interference until the time had passed for that plan of treatment.

**The Death of Dr. Lorenzo W. Elder, of Hoboken, N. J.**, took place on Wednesday, the 11th inst. The deceased, who was in his seventy-third year, had for many years been a much respected practitioner in Hoboken.

**The Buffalo Medical and Surgical Association.**—The special order for the meeting of Tuesday evening, the 10th inst., was the reading of a paper on Some Sources of Error in Obstetric Diagnosis, by Dr. P. W. Van Peyma.

**The Medical Association of Central New York** will hold its twenty-fifth annual meeting in Syracuse, at the Empire House, on Tuesday, the 31st inst.

**Thymacetin.**—"Hofmann, of Leipzig, applies this name to a derivative of thymol bearing the same relation to the latter which phenacetin does to phenol. Its chemical composition is represented by the formula  $C_{16}H_{21}NO_2$ . It is a white, crystalline powder, difficultly soluble in alcohol. It has hypnotic properties."—*Druggists' Circular and Chemical Gazette*.

**Changes of Address.**—Dr. Austin Flint and Dr. Austin Flint, Jr. to No. 60 East Thirty-fourth Street; Dr. James A. Nichols, to No. 143 West Thirty-fourth Street.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 1 to May 7, 1892:*

WOLVERTON, WILLIAM D., Lieutenant-Colonel and Assistant Medical Purveyor, is granted leave of absence until July 10, 1892.

APPEL, AARON H., Captain and Assistant Surgeon, is relieved from duty at Fort D. A. Russell, Wyoming, and will report in person for duty to the commanding officer, Fort Buford, North Dakota, relieving CABELL, JULIAN M., Captain and Assistant Surgeon, who will then report in person for duty to the commanding officer, Fort D. A. Russell, Wyoming.

CRAMPTON, LOUIS W., Captain and Assistant Surgeon, is relieved from further duty at Fort Townsend, Washington, and will report in person to the commanding officer, Fort Spokane, Washington, for duty at that station.

BALL, ROBERT R., Captain and Assistant Surgeon, is relieved from further duty at Fort Spokane, Washington, and will report in person to the commanding officer, Fort Townsend, Washington, for duty at that station.

BRADLEY, ALFRED E., First Lieutenant and Assistant Surgeon, will, upon the arrival of Acting Assistant Surgeon GEORGE D. DESHON at Columbus Barracks, Ohio, return to his proper station (Omaha, Nebraska).

MC CREERY, GEORGE, Captain and Assistant Surgeon. The leave of absence granted for seven days is extended fifteen days.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending April 30, 1892:*

HENEBERGER, L. G., Surgeon. Detached from the U. S. Steamer Iroquois and granted three months' leave of absence.

PAGE, J. E., Assistant Surgeon. Detached from the U. S. Steamer Iroquois and ordered to the Receiving-ship Independence at Navy Yard, Mare Island, California.

WAGGENER, J. R., Surgeon. Detached from the U. S. Steamer Kearsarge and Naval Hospital, New York, and placed on waiting orders.

**Marine-Hospital Service.**—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the three weeks ending May 7, 1892:*

BAILHACHE, P. H., Surgeon. Detailed as chairman of boards for physical examination of candidates for promotion and appointment, Revenue-Marine Service. April 26 and May 3, 1892.

MEAD, F. W., Surgeon. Detailed as chairman of board for physical examination of candidates for appointment, Revenue-Marine Service. May 5, 1892.

KALLOCH, P. C., Passed Assistant Surgeon. To proceed to Providence, R. I., on special duty. April 29, 1892.

KINYOEN, J. J., Passed Assistant Surgeon. Detailed as recorder of board for physical examination of candidates for appointment, Revenue-Marine Service. May 5, 1892.

STONER, J. B., Assistant Surgeon. Ordered to examination for promotion. April 20, 1892.

DECKER, C. E., Assistant Surgeon. Detailed as recorder of boards for physical examination of candidates for promotion and appointment, Revenue-Marine Service. April 26 and May 3, 1892.

GARDNER, C. H., Assistant Surgeon. To report to Commanding Officer, Revenue Steamer Rush, for duty. April 18, 1892.

*Promotion.*

WHEELER, W. A., Surgeon. Commissioned as Surgeon by the President. April 20, 1892.

**Society Meetings for the Coming Week:**

MONDAY, *May 16th*: New York Academy of Medicine (Section in Ophthalmology and Otolaryngology); New York County Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, *May 17th*: Missouri State Medical Association (first day—Pertle Springs); Illinois State Medical Society (first day—Vandalia); Pennsylvania State Medical Society (first day—Harrisburg); New York Academy of Medicine (Section in General Medicine); New York Obstetrical Society (private); Medical Societies of the Counties of Kings and St. Lawrence (annual), N. Y.; Ogdensburgh, N. Y., Medical Association; Hampden, Mass., District Medical Society (annual—Springfield); Baltimore Academy of Medicine; North Carolina State Medical Society (first day—Wilmington).

WEDNESDAY, *May 18th*: Iowa State Medical Society (first day—Des Moines); Missouri State Medical Association (second day); Illinois State Medical Society (second day); Pennsylvania State Medical Society (second day); New York Academy of Medicine (Section in Public Health and Hygiene); Northwestern Medical and Surgical Society of New York (private); Medico-legal Society, New York; Harlem Medical Association of the City of New York; New Jersey Academy of Medicine (Newark); North Carolina State Medical Society (second day).

THURSDAY, *May 19th*: Iowa State Medical Society (second day); Missouri State Medical Association (third day); Illinois State Medical Society (third day); Pennsylvania State Medical Society (third day); New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private); North Carolina State Medical Society (third day).

FRIDAY, *May 20th*: Iowa State Medical Society (third day); Pennsylvania State Medical Society (fourth day); New York Academy of Medicine (Section in Orthopaedic Surgery); Baltimore Clinical Society; Chicago Gynaecological Society; North Carolina State Medical Society (fourth day).

SATURDAY, *May 21st*: Clinical Society of the New York Post-graduate Medical School and Hospital.

## THE LONDON TEMPERANCE HOSPITAL.

LONDON TEMPERANCE HOSPITAL, HAMPSTEAD ROAD, N. W., }  
LONDON, April 12, 1892. }

To the Editor of the *New York Medical Journal*:

SIR: In your issue of April 2d I see a paragraph under the title of Ether as a Stimulant, in which reference is made to the *Lancet* as the authority for stating that in "a certain English temperance hospital" ether is used instead of alcohol.

As this institution is the one referred to, I am sure I can rely upon your sense of justice for the insertion of these lines, in which I wish to give the strongest denial to the charge implied in the words of the *Lancet*—a charge resting entirely on the report of an anonymous correspondent of a London evening paper.

In this hospital there is no need to substitute ether for alcohol, as the latter can be used by the medical staff when they so decide.

Ample evidence has been laid before the *Lancet* of the falsity of the statement to which it so erroneously gave credit, and an editorial *amende* has appeared in its pages.

DAWSON BURRS, D. D.,

Hon. Secretary, London Temperance Hospital.

**Proceedings of Societies.**

## NEW YORK ACADEMY OF MEDICINE.

SECTION IN PUBLIC HEALTH, LEGAL MEDICINE, AND MEDICAL AND VITAL STATISTICS.

Meeting of March 16, 1892.

Dr. HENRY D. CHAPIN in the Chair.

**The Infliction of the Death Penalty by Electricity.**—

Dr. CARLOS F. MACDONALD read a paper on this subject. (See pages 505 and 535.)

Dr. A. D. ROOKWELL said that electricity was, in its management, a capricious agent. It might sometimes, through causes unforeseen, fail at the critical moment. He had seen an illustration of this in some experiments at Clinton Prison last year. A bull was about to receive the impact of 1,000 volts, but, through a defect (entirely preventable, it was true), the pressure instantly fell to half the original voltage. If this had occurred during an execution the criminal not only would not have been killed, but might not have been rendered unconscious even. But, as compared with hanging, the use of electricity was, in the interest of humanity, a step in advance. Suppose, for example, that it had always been customary to execute by electricity instead of by hanging, and some one had suggested that the former method be abolished and the latter substituted; that a method practically instantaneous, painless, without mutilation, and unattended by convulsions or any distressing outward manifestations of pain, be replaced by one that failed to extinguish life in less than ten or fifteen minutes, which in many cases was possibly attended with torture, and where the convulsive manifestations were horrible to witness—such a suggestion could not have the slightest title to serious consideration; as a matter of fact, it would never be offered. In connection with Dr. MacDonald and Professor Laudy, the speaker visited the different prisons of the State and experimented upon a large number of animals, to determine the best methods of carrying out the provisions of the law. They had found that a thousand volts was sufficient to kill the largest animal, and they had therefore thought it certain that no hu-

man being could resist that strength of current. Subsequently, to their surprise, it had been demonstrated that a greater pressure was necessary to destroy vitality in a man weighing one hundred and fifty pounds than in one of the lower animals weighing a thousand pounds or more. This, it seemed to him, should be attributed to causes both physical and psychical. The body conducted electricity by virtue of its saline solutions. Fright drove the blood away from the surface to the central portions of the body. When a man was placed in the chair he was necessarily terribly frightened, and the result was that the surface tissues were unnaturally dry, and therefore inferior conductors. He also knew what was coming, and every nerve and muscle was tense with involuntary resistance. It seemed reasonable to believe that this nervous tension operated directly to impede the action of the electricity. A suggestive confirmation of this statement was afforded by the greater readiness with which men were killed when accidentally receiving the electric current. Being in an entirely normal condition as to both mind and body, they succumbed to the shock almost as readily as the lower animals. When a man was executed by electricity he became entirely motionless; there was not even the outward appearance of suffering, and, aside from the fact that a human life was being taken, there was little that was revolting in this method of execution. It was to be hoped that in time electricity would replace the rope in all the States.

Dr. W. J. MORRISON said that, unlike the reader of the paper of the evening and many of those who were to discuss it, he had not had the advantage, if advantage it might be, of witnessing the infliction of death by electricity; and he had not been aware of the points to be touched upon until after he had listened to the paper. Regarding the objection that had been made to physicians' discussing the question of how to kill human beings, it seemed to him that this discussion might be considered analogous to a discussion on the best method of performing a justifiable fœticide—a subject that would not be out of place in any medical society. Regarding the present topic, that electricity killed the subject was beyond question. The question of prime importance was, Did it kill humanely? for it was upon this ground, if he recollected, that this bill had been passed and that the continuance of the method was demanded. From this point of view they were justified in examining critically the methods employed to kill. Such an inquiry also naturally involved the question of how electricity killed and why. To kill human beings would seem to require a due adjustment of the relations between voltage and ampèreage—viz., a relation translatable into the largest possible horse power. It was not voltage alone that killed, for we might receive with impunity a current of 100,000 or many more volts from a Holtz machine, if the current was uninterrupted. And ampèreage alone did not kill, for a continuous current gradually increased from a minimum might be readily endured which, if interrupted, would cause violent shock to nerve and muscle and probably death. Neither did alternations alone kill, for a Tesla dynamo gave 20,000 alternations a second (the voltage also running up to 50,000); and yet no shock was felt from this current when it was passed through a human being. But it was a proper adjustment of voltage, of ampèreage, and of alternations that killed, and it certainly did not appear that this adjustment had yet been reached. If it had been, death would be instantaneous and not, as now, prolonged through several applications, or even through a prolonged single application. Take, for instance, the application in the case of McElvaine; it had been one of 1,600 volts, giving from two to three ampères, during fifty seconds. From a humane point of view, fifty seconds was an age to die in, if the subject could be killed in one fiftieth of a second; and the speaker had no doubt that he could be.

It was undoubtedly the watts—i. e., the horse power—that killed. Electric power was the product of the volts multiplied by the ampères. The watt was the name of the unit employed to express this product, and it was equivalent to  $\frac{1}{746}$  of a horse power—in other words, 746 watts were equal to one horse power. Referring to the example of 1,600 volts and 2 ampères, and taking the formula  $H. P. = \frac{\text{volts} \times \text{ampères}}{746}$ ,  $H. P. = \frac{1,600 \times 2}{746}$

= about 4 horse power. The question, then, was, if 1,600 volts and 2 ampères took 50 seconds to kill the criminal beyond doubt, why not employ a horse power that would kill him in one fiftieth of a second or less? This would simply require a readjustment of the parts of the electrical outfit used to kill with—viz., an increase of voltage obtained by strongly exciting the field of the dynamo, by increasing the number of revolutions, and by decreasing the resistance (by enlarging the electrodes and preparing the surface of the skin by removing the oils). The electrodes now used presented only about one hundred square centimetres of surface, or about three inches and three quarters. An example of what might easily be done would be to use a voltage of 3,000 instead of 1,600, to increase the size of the electrodes, and to produce 10 instead of 2 ampères. This was a very moderate estimate. Again, using the formula

$$H. P. = \frac{\text{volts} \times \text{ampères}}{746}, \text{ we should have } H. P. = \frac{3,000 \times 10}{746}$$

= 40 horse powers—in other words, 40-horse-power death instead of 4-horse-power death. There could be no question as to which would be the more nearly instantaneous, and therefore the more humane. The 40-horse-power current would kill in a fraction of a second, as against the possible agonizing seconds of the prolonged application. But, granting the most absolute perfection of electrical machinery for killing the criminal, the question might properly arise, *Was death by electricity instantaneous?* This involved the question of *how electricity killed*. Did it kill by electrolysis, by molecular disintegration; or physiologically, by producing functional death of the part? The current that killed could only be conveyed through the fluids of the body by electrolytic conduction, which meant a decomposition of molecules. But since there was no discoverable evidence of this decomposition, he was obliged to say that recombination took place as fast as decomposition, and that by this change of partners of the atoms of the molecule the current was conveyed with no loss of integrity to the fluid and the tissue except immediately at the surface of the electrodes, where free electrolysis occurred. Since, then, microscopically, no actual decomposition of fluids and tissues could be proved to have taken place, and since, electro-chemically, no such decomposition need be expected, he could hardly see how it could be maintained that death was caused by electrolysis. There was, however, one point of view that might warrant one in attaching importance to electrolysis. In tissues the current was carried mainly by the salts: the tissue acted like a solution of its salts. There was, therefore, a constant decomposition of the salts, with an accumulation of the products of the decomposition at the electrodes. This meant a diminution of the salts in the intrapolar region. How much robbery of its salts would a tissue stand before it became a dead tissue? The salts varied from one to two per cent., but this amount was in intimate union with the proteid constituents of the tissue and was essential to their life. Electrolysis might, therefore, kill without exhibiting any signs of decomposition to the eye, even aided by the microscope, by removing the inorganic constituents to such a degree that functional life ceased. An interesting point in resistance was to carefully wash the oil out of the skin. He made a suggestion as to a change in the position of the electrodes. A point made by the microscopist in searching in ganglionic cells for evidence of

fatigue or exhaustion was that the nucleus lost bulk. If death was due to the sudden arrest of physiological function, there would be no time to produce these changes in the nerve cells. These latter had the usual functions of all cells; slowly irritate them, as in Hodge's experiments, and they would change, but act on them with an electric current, and the change was imperceptible. While this method was in the line of progress, he thought that we might as well go further and give chloroform, as Wilder had suggested.

Professor LAUDY, of Columbia College, had been called to measure the machines previous to their acceptance from the contractors. With one exception, the motive power had been perfect. The failure of the Kemmler execution had been no surprise to him, as the plant at the Auburn State Prison had been condemned, and he had remarked that failure would result there from the sudden drop of potential in the dynamo. Electro-motive force was not under complete control, and one could not raise or lower it; the prison machines had been designed for 1,000 volts, and they had increased them to 1,800—as high as was judicious. The engine motion was conveyed by belting, and there were the dynamo, wires, switchboard, etc., each time there was a new contact, increasing the chance of failure.

Mr. W. J. JENKS was the next speaker. (See page 542.)

Dr. ANDREW H. SMITH said that, while it was, of course, highly desirable that at the points of contact the resistance should be reduced to a minimum, yet, when the current was once within the body, its lethal effect would be in direct, not reverse, proportion to the resistance it encountered. If the vital organs were perfect conductors, offering no resistance, there would be no effect from the passage of the current. In this respect the lethal resembled the mechanical, the electrolytic, and the thermal actions of electricity. The result in each case would be in proportion to the detention of the fluid in the substance acted upon. The speaker said that, in his judgment, the deadly effect of the briefest possible contact in accidental cases, in which also the voltage was often comparatively low, was due to the concentration of the current in a very narrow path. Enlarging the surface of the electrodes, therefore, would, he believed, be a mistake, unless the volume of the current was proportionately increased. As to the humanity of this method, it had been his lot to witness six executions—one by the guillotine, one by shooting, and a triple military execution by hanging, in which the drop was used, and one other by hanging where the culprit was jerked up by the falling of a weight. At four of these he had been present in the performance of military duty. All had been horrible and revolting beyond description, and the contrast with what Dr. MacDonald had described convinced him of the enormous advance that had been made by the introduction of the new method.

Dr. A. JACOBI said that Dr. MacDonald had dealt with this disgusting topic in a better manner than he had thought it could be done; but it should not be considered by any medical society, for the purpose of medicine was to save, not to take life. Physicians had always been condemned for experiments on the human body. Only a few years ago a well-known physician had been condemned for making some localization experiments on an exposed brain.

Dr. ROCKWELL said that the criticism seemed severe; in obstetrics sometimes life was taken to save life.

The CHAIRMAN did not consider that he had admitted a paper that was not entitled to a hearing in his Section. The laws of the State provided not only for that method of execution, but also for the presence of physicians. Dr. MacDonald had pursued this work as a State official in a department that had certainly to do with legal medicine, and so long as such provisions were on the statute books of the State they would—while the

present incumbent was chairman—have a hearing in this Section.

Dr. MACDONALD said that he agreed with Dr. Morton that death should be produced as rapidly as possible. The present apparatus was crude, and he had recommended that the central prison be supplied with a proper dynamo, if the use of this method was to be continued. Regarding the employment of chloroform as less offensive, he would simply recall the familiar struggles of the persons to whom that drug had been administered. He had no apology to offer for his work, as it was in the nature of humanity. The subject had been an unpleasant one to him, one that he had had to take up by request of his official superiors, and his paper was a farewell to the subject, as his further aid was not needed.

## Book Notices.

*Manual of Operative Surgery.* By FREDERICK TREVES, F. R. C. S., Surgeon to, and Lecturer on Anatomy at, the London Hospital, Member of the Board of Examiners at the Royal College of Surgeons. Two volumes, medium 8vo, with Four Hundred and Twenty-two Illustrations. London: Cassell & Co., 1891. Pp. 775, 775.

THE field of surgery has come to be so extensive, and the methods of operation have become so numerous, that it is impossible for a work on general surgery to contain even a comparatively full list of them from which the reader may make a choice, unless it runs into encyclopedic proportions. It has therefore become necessary that we should have special works on the art of operating. Jacobson, in his admirable work, has led the way more recently in this line of literature, and now comes this more pretentious effort of a noted English surgeon. Books of this class must of a necessity be more or less compilations, but the present one bristles with originality in almost every section. The author makes experience his guide in approving or disapproving of an operation, and does not allow himself to be led off by the favorable statistics of the originators of different procedures. Conscientiousness is exhibited in the very first chapter, *The Patient*, showing that he is first in the author's thoughts, and not the brilliancy or feasibility of the operation. Is he able to undergo the operation? Will he be truly benefited by it? and, Is there less risk from the operation than from the disease if left untreated—are questions which must all be answered in the affirmative before operating. After describing the different conditions which should influence one in determining whether to operate or not, and laying down rules for the necessary preparation of the patient for the operation, he turns to the second most important consideration—*The Operator*. Is he capable? Is he prepared? Is he in the proper frame of mind to do this particular operation? "A shakiness of the hand," he says, "may be some bar to the success of an operation, but he of shaky mind is hopeless." "Precision of knowledge, precision of judgment, precision of hand are all needed in a surgical operation." "In the handling of a sharp instrument in connection with the human body a confusion of the intellect is worse than chorea." These are expressions showing how carefully the author has thought over the personal element in an operator. In the succeeding chapter, on instruments, he deprecates the multiplication of them, saying: "Some of the least progressive periods in the development of the surgeon's art have been marked by the prolific production of instruments," and "among the very numerous names of designers of instruments, there are but few belonging to surgeons who are or have been eminent as first-

class operators." It is wonderful to see the immense catalogues of these aids to surgery, when so much can be done with a simple scalpel and forceps. The remarks upon the indiscriminate use of sharp retractors, thereby irritating and mutilating the tissues of a wound, and the suggestion of thread retractors, while not new, are certainly timely. We can not altogether agree with the author in what he calls the "barbarous procedure" of using "the sturdy and dangerous piece of steel," a grooved director. While a clean-cut wound is most desirable, and no doubt heals more rapidly, nevertheless in the hands of those who do not operate constantly, in vascular areas, or in operations involving the peritonæum and abdominal viscera, the director is a much safer instrument than the sharp point of a knife.

Very little is said on the subject of antiseptics in the work. Although advising the strictest adherence to the principles of antiseptic surgery, the author seems to consider the technique thereof a hackneyed theme, and lays down no rules or principles to guide one in these matters. After stating the aims upon which surgeons are agreed in the treatment of a wound, the author proceeds to say: "One surgeon accomplishes these ends in one way and another in another, and the results are equal. . . . New antiseptics appear from time to time upon the scene. They are vaunted as perfect, are diligently employed, and then not a few of them fade away, some very gradually, others with the suddenness of the South Sea Bubble." He shirks the responsibility of taking a stand upon this subject, and this is not in keeping with the rest of his work. He insists on the free access of air to surgical wounds, and never allows a part operated on to be kept in the hot, moist, and often foul atmosphere beneath the bed-clothes. He also uses sponges, instead of gauze or cotton, for dressing wounds, arguing that they do not lose their elasticity when saturated, and thus they persistently hold the parts in close apposition during the whole period of healing. We believe the point to be well taken.

Space will forbid our taking up *seriatim* the different chapters of this interesting book, and could we do so we should find our opinions upon the different sections diverse enough. It is exceedingly irregular in its excellencies; the good far outweighs the bad, but still there is enough of the latter to make a revision and second edition desirable.

The sections on ligations and amputations are perhaps the best in the book, and, without disparagement to others, deserve special notice. In the latter we find an excellent description of, and very just conclusion upon, that remarkable osteoplastic resection known as Wladimiroff's. To save all we can of a limb is a good principle, but to preserve a part which will not only be useless but absolutely in the way of its possessor is certainly unwise if not bad surgery. To us this operation seems to be simply an illustration of surgical gymnastics unjustifiable by its results.

The sections on the surgery of the nerves, and that on tenotomy, are disappointing indeed, as is also that on the surgery of the rectum and anus. This latter may, in fact, be called the poorest part of the book. The author seems to have confined himself to the British works upon these subjects in working up this portion of his book. The methods of Kraske, Bardenhauer, and Levy for excision, the method of Van Buren for proidentia, and the American method of transfixion for hæmorrhoids, are left unnoticed. The great interest and advance in these subjects of late demand that closer attention and more space should be given them in a work of this character.

The second volume of this valuable work begins with a chapter on plastic surgery, and in it we find one of the best accounts of rhinoplasty that it has been our fortune to see. Beginning with the Indian operation, as modified by the German surgeons, which he thinks is the best, the author describes minutely all

the principal operations of this class, including Keegan's, von Langenbeck's, Dieffenbach's, Weir's, the Italian, the French, and other methods. One can not want for a choice of operations or a clearer description of their technique than is here found for complete or partial rhinoplasty. As much may be said for the chapter on operations for cleft palate. The chapter on plastic operations for diseases and deformities of the lips does not compare favorably with the last two mentioned. We are surprised to find described only one each of Serre's and Szymanowski's operations, and that of Burow omitted altogether. A liberal reference to either one of two American works on surgery that we know would have made this section more complete. Readers of this portion of the work will be surprised to see the name Diday substituted for that of Didot as the author of the anterior-and-posterior-flap method for the cure of webbed fingers. This we thought at first an error, but, on investigation, find that the author is correct, and that whatever merit the operation has is due to Diday and not Didot.

In the section on abdominal surgery we have perhaps the fullest exposition of Treves's own personal experience and work, for he has long been prominent as an operator in this line. We can not go over his views *seriatim*, but mention one or two that seem a little out of line with the latest teachings on the subject. He thinks no special preparation of the patient necessary for abdominal section beyond that for any ordinary surgical operation; he believes in the intraperitoneal treatment of the stump in hysterectomy and in the superiority of lumbar over inguinal colotomy. On all these points we dare say he will find many eminent surgeons taking decided issue with him. In this same chapter he uses the name Atloe for that of Atlee as a pioneer in abdominal surgery, but this may be a typographical error.

We have thus noticed at length this important addition to surgical literature, and, if we have criticised somewhat closely, it has been because we have been much interested in the work, and appreciate it very highly. It is, in our opinion, one of the best books in the English language on the subject of operative surgery, and does credit to the energy, conscientiousness, and liberality of its noted author.

#### BOOKS, ETC., RECEIVED.

Treatise on Gynæcology, Medical and Surgical. By S. Pozzi, M. D., Professeur agrégé à la Faculté de médecine, etc. Translated from the French Edition under the Supervision of and with Additions by Brooks H. Wells, M. D., Lecturer on Gynæcology at the New York Polyclinic, etc. Vol. II. With One Hundred and Seventy-four Wood Engravings and Nine Full-page Plates in Color. New York: William Wood & Co., 1892. Pp. xiv-583.

A System of Gynæcology. With Three Hundred and Fifty-nine Illustrations; based upon a Translation from the French of Samuel Pozzi. Revised by Curtis M. Beebe, M. D., Chicago. New York: J. B. Flint & Company, 1892. Pp. viii-17 to 604.

A Treatise on Bright's Disease of the Kidneys: its Pathology, Diagnosis, and Treatment. With Chapters on the Anatomy of the Kidney, Albuminuria, and the Urinary Secretion. By Henry B. Millard, M. A., M. D., Fellow of the Academy of Medicine of New York, etc. With Numerous Original Illustrations. Third Edition. Revised and enlarged. New York: William Wood & Company, 1892. Pp. xviii-322.

Yellow Fever: a Monograph. By James W. Martin, M. D. Edinburgh: E. & S. Livingstone, 1892. Pp. 9 to 56.

Diseases of the Nervous System. By Jerome K. Bauduy, M. D., LL. D., Professor of Diseases of the Mind and Nervous System and of Medical Jurisprudence, Missouri Medical College, St. Louis, etc. Second Edition. Philadelphia: J. B. Lippincott Co., 1892. Pp. 10-11 to 352. [Price, \$3.]

Miners' Nystagmus and its Relation to Position at Work and the Manner of Illumination. By Simeon Snell, F. R. C. S. Ed., etc. Bristol: John Wright & Co., 1892. Pp. x-143.

Transactions of the American Orthopædic Association. Fifth Session, held at Washington, D. C., September 22, 23, 24, and 25, 1891. Volume IV.

Recherches cliniques et thérapeutiques sur l'épilepsie, l'hystérie et l'idiotie. Compte rendu du service des enfants idiots, épileptiques et arriérés de Bicêtre pendant l'année 1890. Par Bourneville, médecin de Bicêtre, avec la collaboration de MM. Cameeasse, Isch-Wall, Morax, Raoult, Seglas et P. Sollier, internes et anciens internes du service. Volume XI. Avec 16 figures dans le texte et 10 planches. Paris: Vve. Babe et cie., 1891. [Publications du *Progrès médical.*] Pp. c-3 to 252.

Hospice de la Salpêtrière. Clinique des maladies du système nerveux. M. le Professeur Charcot. Leçons du professeur, mémoires, notes et observations. Parus pendant les années 1889-'90 et 1890-'91, et publiés sous la direction de Georges Guinon, chef de clinique. Avec la collaboration de MM. Gilles de la Tourette, Bloecq, Huet, Parmentier, Souques, Hallion, J. B. Chareot et Meige, anciens chef de clinique, internes et interne provisoire de la clinique. Avec 47 figures et 3 planches. Paris: Veuve Babe et cie., 1892. [Publications du *Progrès médical.*] Pp. iii-468.

Les nouvelles découvertes en électricité. Histoire d'un inventeur. Les moteurs électriques. Machine dynamo de démonstration. Bijoux électriques lumineux. Éclairage électrique, domestique, industriel et militaire par les lampes électriques. Électricité médicale. Photophores électriques. Micrographie et photomicrographie. Téléphones et microphones. Installation téléphonique domestique. Tricycle électrique. Applications de l'électricité à la navigation fluviale, maritime et aérienne. La navigation électrique, etc. Par G. Barral. Deuxième édition. Paris: J. Michelet, 1891. Pp. xvi-610.

Removal of Adenoid Growths from the Vault of the Pharynx. By H. Hoyle Butts, M. D., New York. [Reprinted from the *Medical News.*]

## New Inventions, etc.

### AN INSTRUMENT FOR THE MEASUREMENT OF THE RESISTANCE IN A STRICTURE.

By E. W. SCRIPTURE,  
WORCESTER, MASS.

WHILE at the University of Leipzig I attended a clinic by Dr. Kollmann on diseases of the genito-urinary system. One point that specially struck me was, that although there was so much difference in the resistance to the dilatation exerted by strictures, yet we had hardly any knowledge of the variation in this respect and no means of measuring it. To attain the means of measuring the resistance I took a dilator of the Oberländer pattern and inserted a spring between the wheel turned by the fingers and the axle that communicates the movement to the dilat-

ing portion. The original form can be approximately seen from the illustration if all to the right of the letter I is covered up. When introduced into the urethra the instrument is closed, but in dilatation the screw I carries forward the bar E, which, being connected by C to the bar D, is obliged to move away from it. B is a joint connecting it to a small piece the other end of which slides in a groove back from A. The extent of the dilatation is indicated in bougie-numbers on the dial J. H is a means of holding the instrument. G is a very small wheel for holding the two flat portions together; a joint is introduced at each end of F. In the modification of the instrument which I have made, the screw I is not moved directly by a large milled head or wheel as in the original; on the contrary, it is prolonged in the form of an axle, and is seen projecting to the right through the wheel N, and carrying a small pointer. N and M are made in one piece; M contains a small clock-spring, which is attached at one end to the axle I, and at the other to the inner surface of M. K is a ratchet-wheel fixed to the axle I, and L is the catch fixed to M. Now suppose the instrument to be closed. Press the lever L so that M N may move freely to its resting place; the spring will then be in a condition of equilibrium, and the little pointer in front of the wheel N will indicate a point which we will call zero. Turn N gently to the right; the dilator will begin to open and the pointer will move over J. There is so little resistance from friction that there will be no noticeable strain on the spring (if of proper strength), and the little pointer will move around with N, always indicating zero, until the instrument begins to approach its maximum dilatation. If, however, at any moment we place an obstruction in the way of further opening—*e. g.*, by pressing the thumb and finger against the two bars D and E—the wheel N will continue to turn, but “I” will stop till the spring is sufficiently spanned to overcome the resistance. The resistance thus bears a definite relation to the tension of the spring; the latter, however, is indicated by the extent to which the wheel N has passed behind the little pointer before the tension was sufficient. The catch L keeps the spring at this tension. Let the face of N be graduated in degrees; then at any time we can find out, by proper application of weights, just how much resistance is necessary in order to have the pointer move over any given number of degrees. This can be done by the physician himself, but it is better for the maker of the instrument to provide a little table giving the various amounts of resistance overcome which correspond to the various positions of the pointer.

The application of the instrument would be in somewhat the following manner: It is introduced closed and without the usual rubber sack over it into the urethra. The rubber sack not only is unnecessary with a carefully made instrument, but it also introduces an insurmountable error into the measurements. N is slowly turned; the little pointer will at most move only a degree or two against its face. When the bars reach the extent of the stricture, the catch L will begin to click over the ratchet-wheel, the pointer J will stop, and N will move behind its pointer. Finally, the clicking stops and both the pointers begin to move; in other words, the spring has reached a tension equal to the resistance of the stricture. The positions of both pointers at this moment are noted. A glance at the table gives the resistance of the stricture.

## Miscellany.

**The Natural History of the Species Medicus.**—A German publication entitled *Zur Naturgeschichte des Medicus*, by “Dr. Risorius Santorini,” illustrated by “Dr. Corrugator Supercilii,” with the motto *Demus juckt, der kratze sich*, has been thus translated by “Famulus”:

CONTENTS.—Historical Introduction. Class I. Medici Academici. Order 1. Professor Ordinarius Consilarius Secretus. Order 2. Professor Extraordinarius. Order 3. Privat-Dozent.—Class II. Specialists. Order 1. The Neurologists. Order 2. The Gynaecologists. Order 3. The Charlatan.—Class III. Birds of Passage. Order 1. The Bath Physician. Order 2. The Clinic Fiend.—Class IV. Medicus Practicus. Order 1. The Lion of the Boudoir. Order 2. The Graduated Jackass. Order 3. The Honest Old Family Physician.

### HISTORICAL PREFACE.

Mankind, as Mr. Darwin states,  
Belongs to the class “Vertebrates.”  
The “Genus Homo” roamed the land  
With sea-horse, mammoth, elephant,  
Before the age diluvian,  
The so-called “prehistoric man.”

But many a learned antiquary  
Thinks these deposits tertiary.  
A miocene discovery  
Would strengthen Darwin’s theory:  
The fact of species-variation  
Would surely find its explanation  
In secrets geological  
Anthropomorphological.  
Then up, ye paleontologists!  
Grasp spade and hammer in your fists:  
Search the coal-measures carefully  
Until the long-sought spoor you see  
In cenozoic gloomy night  
Of our ancestral Troglodyte.

The law of natural selection  
Leads ever upward toward perfection.  
Mankind the effort never ceases  
To propagate the human species.

*Prasumptio est*, the man ideal  
Is slowly now becoming real;  
As each sire grants to son, unmerited  
Virtues he from his sire inherited.  
As type, *Te Deum Laudamus*,  
Is reckoned foremost Medicus.  
For it is known to every proctor  
That Father Adam was a doctor.  
And Henry Faust with equal ease  
Read Scripture and Hippocrates.

And the foul fiend, fresh from damnation,  
Oft aids in biblical translation ;  
Again appears with counsel wary  
As a physician literary.  
He would have penned the great creative process  
"In the beginning was the diagnosis."

Earliest history tells the story  
Of drugs and operations gory.  
And as we learn from Homer's *Iliad*,  
Wounds then were dressed with balm of Gilead ;  
And in Achilles's bold array  
The doctor was an attaché,  
Although *in puncto chirurgie*  
He had not much that's called *esprit*.  
How would our dapper surgeons feel  
Should a slight wound upon the heel,  
Such as befell this general,  
Prove to be instantly lethal ?

The ages crown with recognition  
Hippocrates as a clinician.  
His fame is dear to every heart  
As "Father of the healing art."  
But in his day we note this feature :  
He was empiric as a teacher.  
He had no inkling of dissection,  
Nor of arterial injection.  
Enough—'mid medical afflictions  
We're spared his "positive convictions."

But high above all mean disguises  
The learned Egyptian doctor rises—  
A privy councilor in condition,  
Herophilus, the court physician.  
His research took a new direction,  
He practiced bloody vivisection.  
In which, by Seleukos's permission  
(Physiology then had a mission),  
Material for researches loyal  
Was amply found in debtors royal.  
Peril surrounded noble clients,  
But 'twas a golden age for science.

When thus by royal favor fostered,  
Our colleagues and our calling prospered.  
The *ars curandi* made advance  
And worthy spirits joined its ranks.

This was the time when Galen wrote,  
Whom our own authors freely quote,  
Who, in the sixteenth century,  
Enjoyed infallibility.

In short, the medical profession  
Has proved the truth of evolution.  
Where one the grip has failed to keep,  
Two others are set on their feet.  
And with the multiple diseases  
The corps of specialists increases.

As Darwin's theory proved true,  
The species strong and stronger grew ;  
And from division of their labor  
Established races, each a neighbor.  
How these have thrived and propagated  
Will now in rhyme be briefly stated.

#### Class I.

When several separate generations  
Dwell in harmonious relations,

Though occupying different spheres,  
The species one to be appears.  
We speak of "heterogeny,"  
And call the whole a "colony."

As sample of instinct politic  
Observe the insect-republic  
Which the industrious *Formicide*  
Maintain for rich as well as needy.

Each member of the insect nation  
Pursues a certain occupation.  
A. guards the city from surprise ;  
B. furnishes the food supplies ;  
While C., with eager emulation,  
Devotes himself to copulation.  
That in the "struggle for existence"  
They may present a firm resistance.

In human arts the insect law persists,  
The "colony" as "faculty" exists.  
The "Adjunct" X. strives valiantly  
To guard scholastic dignity ;  
Professor Y., with cautious unction,  
As number C. performs his function ;  
The beast of burden least resistant  
Is the "Instructor" called "Assistant."

#### Order I. PROFESSOR ORDINARIUS CONSILIARIUS SECRETUS.

As chief official in this corps  
We see some hoary Councilor.  
Sometimes he's even "State Physician,"  
Which really is no mean position.  
Early and late, where'er he be,  
His eye is on the Faculty ;  
That the bald heads of fossils hoary  
May not be shorn of former glory ;  
And that no modern heretic  
Some middle-ages bubble prick.  
Because the "honored faculty"  
Presents infallibility.

The theory their wisdom utters  
Is therapeutics for the gutters.  
To keep the caste inviolate,  
Maintain ideas long out of date ;  
To keep youth well refrigerated—  
This is the mission of the aged.

And to prevent things getting mixed  
They like their own offspring well fixed.  
For, if his name be Gray,\*  
He looks around him every way,  
How he can plan that Number One  
May fall to his beloved son ;  
And all the members of the breed  
With pride their comrades supersede,  
So that the dynasty of Gray  
Grows more extensive every day  
By in-and-in maternity  
From now until eternity.

For this, important points appear  
As motives, salient and clear.  
Science takes secondary place  
In elevation of the race,  
When with a title like a steeple  
An old man hoodwinks "common people."

\* Any of the other indifferent colors may be selected, instead of the one here mentioned, according to the chromatic requirements of the reader.

The title "City Inspector"  
 In worth more than a newspaper,  
 To the proud conciliarium  
 With all the high-priced publicum.  
 For a prescription from *his* pen  
 Costs a gold eagle; but then—  
 Ten times the action surely follows  
 Than if the doctor charged three dollars.

Order 2. PROFESSOR EXTRAORDINARIUS.

*The Laboring Family Man.*

From instinct comes the aspiration  
 In mankind for official station.  
 A title renders great assistance  
 In the long struggle for existence.  
 When once he's reached the "Adjunct's" fame  
 He longs for the "Professor's" name.  
 And out of twelve, perhaps eleven  
 No greater boon could ask of Heaven.  
 But here, like as in Holy Writ,  
 Many are called, but few are fit.  
 So, *pour plaisir*, we read and hear  
 Things only which are popular.  
 Science attracts both him and her,  
 Thanks to the efforts of Pasteur.

The public reads with glad surprise  
 The effusions of this Solon wise  
 In every agricultural paper,  
 As well as in the *Gospel Taper*.  
 Which all declare his genius rising:  
 This is "judicious" advertising.

His various "researches" amount  
 Only to swell his bank account.

There's sometimes great utility  
 In fashionable charity.  
 But to all hearts he gains the key  
 By "Lectures on Emergency,"  
 Enhanced, if he possess the nickel  
 The editorial palm to tickle,  
 When great and small will surely read  
 That he is a "great man" indeed.

But genius her great triumph wins  
 When the Professor now begins  
 To bring his daughters under cover  
 By means of eligible lover:  
 Especially if *female* lambs  
 Be the sole product of his hams.\*

Order 3. THE ADJUNCT PROFESSOR.

Salute, my lay, with studied grace  
 The most imposing of the race.  
 As clouds soar o'er the city's pile,  
*He* towers above the "rank and file."  
 "Adjunct Professor" is the name  
 To which this animal lays claim.

A prototype of erudition,  
 It graciously grants recognition  
 To other works of God's creation;  
 But only like a "poor relation."  
 It poses as Hygeia's watchman  
 Upon the walls of learning's Zion.  
 It seizes Nature's blindest riddles,  
 Groups them in systems while it piddles;  
 Its eyes sometimes to mortals sink,  
 Because the beast must always think.

Anon it shows on forehead high  
 The wrinkles of philosophy;  
 And trims, in aping the Professor,  
 Its beard, designed by the hair-dresser.  
 The above is but the fœtal state  
 Of what develops soon or late,  
 According to the elements,  
 Into "Surgeon to Out-patients."  
 The earlier is the stage lateu;  
 This is the full development.

But meanwhile in his surgery  
 There is a cloak of mystery.  
 And mystery alone is able  
 To grant a halo round the Schaedel.

What virtue would the halo have  
 If every layman could perceive  
 The veil which hides the goddess-form?  
 That was the reason that in Rome  
 The Haruspices took their rise  
 To throw dust into prying eyes,  
 And pull the wires behind the curtain.

With the first blush of coming day,  
 Our Doctor starts upon his way.  
 The hospital first claims his skill,  
 Where the Interues with eager will  
 Pulse, respiration, temperature  
 Have taken with precision sure;  
 Have tried each patient's fragrant urine  
 To see if it contains hippurin;  
 Secured the auamnesia,  
 And booked the whole with pious care;  
 For it is far beneath Docents  
 To investigate the elements—  
 Charms for philosophers like these  
 Have only the "higher analyses."

"Clinical material" useless is,  
 Except to build hypotheses,  
 Which, comet-like, blaze one by one  
 Upon the clinic's horizon.  
 A novel remedy is found;  
 With great discretion handed round,  
 Quickly it everywhere is tried.  
 The special journals all describe  
 The clinical experiments;  
 Each one the other compliments,  
 Things thus four weeks at most remain;  
 We never hear of it again.

The discoverer smiles when'er alone  
 "By Jove! it's pleasant to be known!"

When this mild comedy is played,  
 Quickly another scene is laid:  
 Now thallin, next day pyridine,  
 And the day after urethane!  
 And even thou, potent cocaine,  
 Into what mischief hast thou been  
 That man should show thee such abuse,  
*Per os et anum* introduce?

Though we the fraud at length observe,  
 The plan shows method and shows nerve.  
 Hence people call this deviltry  
 The "only rational therapy."  
 But even the man of sense acutest  
 Can win no fame as therapist,  
 For just now Science her favor yields  
 Only in pathognostic fields.

\* *I. e.*, loins.

The claims of Science now demand  
 Quasi "researches" from his hand.  
 Therefore he pays his amorous court  
 To bacteriology; in short,  
 He tries by fine hypotheses  
 Thus to account for all disease.  
 And being "modern," "just announced,"  
 No "want" was ever more pronounced,  
 Each downy, newly-hatched Docent  
 Has need of "special experiment."

Each "Adjunct's" head presents a lump  
 Labeled, "Investigations-bump."  
 The suffering rabbit is infected,  
 All kinds of gurry are injected,  
 And soon "pure cultures" we may see.  
 Oh, Koeh! What do we owe to thee!

Nothing now aids the "cause eternal"  
 As does a "liberal medical journal,"  
 Which kindly tells the "rank and file"  
 What this great mind achieves meanwhile.  
 Often we slumber o'er the letter—  
 His motto is, "The more the better."  
 Twelve columns upon *Gonococcus!*  
 What need in hospitals to look us?

It also causes him no sorrow  
 If in the same review to-morrow  
 By Dr. X. the sham's exposed,  
 And all his canting fraud disclosed.  
 Each one "discovers" what he can  
 To make a name or mar a man.

His glory lasts about four weeks.  
 Afterward no one of it speaks.  
 Each folly runs its course specific;  
 And people call this "scientific."

So slowly passes year by year  
 Of Docent's suffering career.  
 For, ah! with all his application,  
 He fails the longed "Professor's" station;  
 Thereby our Docent's entire stage  
 Comprises but the larva age.  
 For his own merit, of all things,  
 Is suited least for growth of wings.

Make but one other change in life;  
 Pay court to the Professor's wife;  
 With higher aims strive valiantly  
 To rise within the "colony."  
 A kindly warmth your limbs will thaw  
 When you've become a son-in-law.

#### Class II. THE SPECIALISTS.

Even in our calling is provided  
 That higher art should be divided.  
 Each province is well isolated,  
 For "science" is so complicated;  
 Smith leans to neurotherapy;  
 Jones more to gynecology;  
 Currie's a dentist and my own,  
 And skin disease is cured by Cohn.  
 Each specialist is known to be  
 Unquestionable "authority."

#### Order 1. THE NEUROLOGIST.

*Medicus sanitarium neuropathicum privatum dirigens.*

A large rôle in disease to-day  
 Neurasthenia is known to play.

At times with speed like that of steam  
 It rushes through life's vivid dream.  
 The pallid youth in tenderest years,  
 While yet scarce dry behind the ears,  
 Wrestles with Bacchus and Gambrinus,  
 With nicotine and goddess Venus.  
 The maiden, in steel corset tight,  
 Like the Nyanza, blooms at night;  
 Inflames her chaste imagination  
 With scenes of Zola's mild creation;  
 Acquires as sign of culture then—  
 For this belongs to "upper ten"—  
 Chlorosis and amenorrhœa  
 Combined with "reflex diarrhœa."

A nervous female *in that line*  
 Surpasses all the Muses nine.  
 This trouble is conveniently  
 Peculiar to the "Quality."  
 It stands the doctor in good stead  
 As a means to win his daily bread.

The doctor is a pure clinician  
 In his rude, embryo condition,  
 But he attends most punctually  
 The lectures on psychiatry.  
 Then modestly his name appears,  
 As "Specialist for many years,"  
 To which he adds, with zeal astute,  
 A Neuropathic Institute,  
 "In the most charming region" lives  
 [Particulars our pamphlet gives],  
 Forests with fragrance of pine cone,  
 Atmosphere laden with ozone,  
 From northern blasts by hills protected,  
 Romantic picnic tours projected;  
 Around the Home a noble ground;  
 Board reasonable [£100].

The doctor wins his way with ease  
 If he the fair, frail sex can please.  
 Platonic freedom from all passion  
 Is his most valuable possession.  
 For "confidence is slowly won  
 In nervous patients." [Nettleton.]

The therapy is "rational"  
 Only when "individual,"  
 But the brave doctor has at hand  
 Three mighty adjuncts on demand.  
 These will respond with vigor bold  
 When water hot and water cold  
 And even electricity  
 Will not secure felicity;  
 In treatment, they're ace, king, and queen,  
 Bromkali, chloral, and morphine.

#### Order 2. THE GYNÆCOLOGIST.

*Medicus parfumatius.*

Dip, gentle Muse, as "*dame d'honneur*,"  
 Thy magic wand in "*eau de mille fleurs*";  
 Lead me as guardian angel on  
 Into the incense-filled salon  
 Where, gently dimmed, the light of day  
 Through gauzy curtains makes its way;  
 Where ornaments, in taste the best,  
 The heaving bosom's pangs arrest;  
 While Rubeus's deathless "*Garden of Love*"  
 Directs their thoughts to "things above."

Here the fond patients timid wait  
For the expected *tête-à-tête*  
With him they love, while yet they fear;  
The deity they worship here.

In true artistic nonchalance  
The picture of male elegance,  
A velvet robe of pattern rare,  
With "scientific" beard and hair,  
While on his fingers soft and white,  
Gems sparkle in reflected light.  
He sits as if in marble cast—  
Nature's best work, as well as last.  
From top of head to plantar hollow  
As Æsculapius and Apollo,  
To Madam faithful to advise,  
To Magdalen a father wise,  
He hears with patience the confession  
Of honor's breach and love's wild passion;  
With "Ah!" and "Oh!" "what shall I do?"  
[Compare with Goethe's *Faust*, act two.]  
On this one point without cessation  
He centers all his application.  
Ten dollars is the usual fee;  
It's double this sum frequently.

If, spite of all, the cure's delayed,  
The "springs" serve as a lightning rod.  
Who knows the "waters" knows their names,  
Where cures are sought by gentle dames.  
At Hot Springs, Baden, Saratoga,  
Sibyllenort, Ems, Lake Ladoga,  
Our doctor stands on best of terms  
With all the various hotel "firms."  
Carlsbad is now most highly prized,  
By ladies greatly patronized.  
Charms there are found which please the sense  
With which at home they must dispense.  
Ye Gods above! women are wise!  
Oh! husbands! have you then no eyes?

### Order 3. THE ADVERTISING QUACK.

#### *Medicus charlatan.*

To former times we're carried back  
By contemplation of the quack.  
Well has this parasitic trash  
Learned how to peddle spurious cash.  
On open squares all ills of man  
Were "treated" by the charlatan,  
Aided by a street mendicant  
Who lured the sufferers to his tent.  
The "enlightened press" with powerful sway  
Serves as his mendicant to-day,  
Where every page the eye displeases,  
With "Specialist in skin diseases."  
For secret sins of every kind  
He only knows the cure to find.  
The assistant loudly shouts the praise  
Of "Cohn, chief doctor of our days."  
And Itzig wrote with pen which ran good  
A treatise on *Decay of Manhood*.

The cure is wrought by a "specific."  
The treatment's purely "scientific,"  
But acts with greater certainty  
When aided by an advance fee.  
"Relations strictly confidential,  
Absence from business not essential."

Practice of this kind pays quite well.  
The doctor knows his clientèle:

The student and the circus-rider,  
The hogreave and the humble schneider,  
With troubles of a certain class,  
Into his hands as patients pass.  
It is well known through all the town,  
His only terms are "money down."  
And as each case is quickly stated  
To be "uncommon complicated,"  
The patient finds at last the fee  
Quite a financial penalty.  
The sufferer can not get away;  
For when he nothing more can pay,  
As token of his penitence,  
The villain stakes his confidence.  
By "confidence" he keeps his "jobs,"  
By "confidence" the patient robs,  
By "confidence" his dupe denounces,  
When he at last the doctor "bounces."  
Therefore this kind of mountebank  
Is numbered in the "Vampire" rank.

### Class III.

#### Order 1. BIRDS OF PASSAGE.—THE HYDROPATHIC SPECIALIST.

#### *Medicus balneus elegans.*

In spring, when from the Nile's green shore  
The feathered warblers northward soar,  
When amorous nightingales are singing,  
And swallows their weird flight are winging,  
When storks stride through the reedy bogs  
In search of winter-fattened frogs,  
The bath-physician, like the other  
Gay birds of passage, leaves his cover.

His winter beard falls to the razor,  
For fashions new he leaves his measure,  
Then circulates his "summer card,"  
St. Moritz, Carlsbad, Martha's Yard.

Nature, scarce waked from winter chill,  
Shivers in rime upon the hill,  
While in the sheltered valley deep  
Graze undisturbed the fleecy sheep.

Already in the leafy grove  
The finches carol notes of love,  
While peals from every hostelry  
The "sanitary orchestra."  
Behold! The tardy signs appear!  
Ho! Invalids, the spring is here.

From north and south, from east and west,  
Now comes the pale-faced summer guest.  
From Maine the manufacturer,  
From Buffalo the beer-brewer,  
A colonel fresh from Bowling Green,  
From England Lord and Lady Spleen.

And then, with rank and title higher,  
From Russia, Poland, Turkey, Speyer  
[Now, Doctor, play most carefully],  
The princely crowd of -koff and -ky.  
And finally—oh, height of bliss!  
His Highness, "Serenissimus."

Take courage, Doctor, it's your mission,  
"Highness" will make you Court-physician.  
I see already on your breast  
The "order-medal," softly pressed,  
Of "Lippe-Detmold" and "Reuss-Schleitz."  
Ambition now takes loftier flights;  
One further gracious act of power,  
And, lo! the Privy Councillor!

Now as you write each proud initial  
You'll say "The baths are beneficial."

To this you may with right aspire :  
The laborer should have his hire.  
Such a reward begets renown ;  
Such merit should receive its crown.

Then head aloft ! nor feel a care,  
However your colleagues may stare.  
Their envy should not mar your joy,  
No earthly bliss but has alloy.  
You've won distinction through the State  
By means of sodium carbonate.

Of hydrotherapy the staff,  
See "interesting monograph."  
[A learned work, and finely bound,  
At all the news stands to be found  
By the beloved publicum.]  
It treats of waters and of *him*.

Highly important 'tis to guard  
In health resorts the promenade,  
For only *præsentate medico*  
Can healing from the waters flow.

At break of day, and full of grace,  
Our Medicus is at his place,  
In latest-modeled habitus,  
With silver buttoned baculus.  
Thus he approaches, brave, sedate,  
In all respects immaculate.

At duty's bidding see him stand,  
With gold chronometer in hand.  
Here, Countess's pulse must be inspected ;  
There, Highness's tongue must be projected ;  
Now lifts the hand to ask a swell  
If "Excellency rested well."

"Two glasses, Marquis ? Hold, I pray !  
Your health requires that I cry nay !  
Your noble stomach *debonnair*  
One and a half at most can bear."  
"I beg your pardon, Admiral,  
To-day, but one hour on the mall ?  
Free exercise is Nature's balm,  
Excess can lead to naught but harm."

"No, Countess, it is hard, I own ;  
Nothing at present but bouillon !"

"Excuse me, Baron, gracious Heaven !  
Already it is near eleven !  
His Highness waits ; *à la lever*,  
*Au revoir* at déjeuner !"

#### Order 2. THE IMMATURE CLINICAL FIEND.

##### *Medicus fere omnia sciens.*

When science is to be acquired  
The fruits of travel are desired.  
The man of means may go for pleasure,  
The merchant, sea and land must measure—  
May gold reward his energy ;  
His Lordship travels from ennui.  
The bashful newly married pair  
Travel they know not why or where.

By higher aspirations fired,  
The doctor travels far and wide ;  
His portmanteau is packed with care,  
His "old man" must the drafts prepare,  
And thus he journeys—grace divine—  
Toward Vienna's classic shrine

As hastening to his waiting bride.  
His bosom swells with conscious pride,  
Celebrities of every land  
Now as "colleague" extend the hand.

As a "distinguished foreigner"  
He has a seat in the parterre,  
And listens with upturned proboscis  
To the symptomatic diagnosis ;  
At times he smiles in condescension,  
To show his lofty comprehension.

Thus stalks this scientific vulture,  
This greedy carrion crow of culture,  
To clinics uninvited turning,  
A windbag of promiscuous learning,  
Till finally he moves his quarters  
Near where earth's frail and fallen daughters  
Promise "material" all too free  
For living craniotomy.

Nowhere in surgical domain  
Would be allowed this septic bane.  
Here meanwhile he may boldly try  
His virgin forceps to apply  
As soon as he with silver balm  
Has crossed the gentle midwife's palm.  
The assistants also fully know  
The meaning of a *quid pro quo*.  
And when the labor is concluded  
He seeks a restaurant secluded  
Where Bacchus, Venus incarnate,  
Assist him to recuperate.

Anon at home we see him landing,  
A man of "ripened understanding."

#### Class IV. MEDICUS PRACTICUS.

##### Order 1. THE LION OF THE BOUDOIR.

The doctor makes a gain emphatic  
By aping ways aristocratic.  
Especially in the female world  
Much hangs on how the hair is curled.  
Whoever then would be in tone  
Must make these manners all his own,  
Which act as "open sesame,"  
For those who "upper ten" would be.

Always in faultless taste arrayed,  
Reeking with perfume and pomade,  
With diamond ring, silk hat, glasses,  
Shoes patent leather, gold pince-nez ;  
Upon the hour of the visite  
He waits upon the "haut élite."  
And if with wit and *bon esprit*  
He ornaments the *causerie*,  
He knows the time not far away  
For audience in *négligé*.

With gossip from the matinée,  
From corso, grand ball, and soirée,  
He drives away through eye and ear  
All that her fancy had to fear.  
Till soon, from treatment without end,  
He is a most dangerous family friend :  
He is a living neverslip  
In point of close companionship.  
Round noble minds he weaves his toils  
Close as the gliding serpent coils,  
And cultivates with ardent passion  
The vices of the world of fashion.

The arts of gaming he has learned,  
 To feats of chance his hand has turned,  
 The jockey club he also prizes,  
 And loud his winnings advertises ;  
 For knowledge of the Derby races  
 The climax on attainments places.  
 The news in latest buffet scenes,  
 Last scandals of the lyric queens ;  
 The newest " bon mots " of the street  
 He gives, the kernel and the meat,  
 With effort which no limit knows  
 Repeats the tale where'er he goes.  
 Thus only in the " higher walks " of  
 Of life this gaudy creature stalks.  
 Cajoled by disappointed dames  
 He thus a certain standing claims.

*Applaudite*, then, colleagues all !  
 You all would suffer should he fall.  
 Science must rise, cost what it may,  
 E'en though her pedestal be clay.

Order 2. THE GRADUATED JACKASS.  
*Medicus asinus.*

In ancient times the doctor's gown  
 Was like an heirloom handed down.  
 But even the garment most sublime  
 Grows shabby with the lapse of time,  
 And gowns, like other earthly wares,  
 Are also variable affairs.  
 Oft 'neath the doctor's hat appears  
 A prominent pair of ass's ears.

The first-born son is now sixteen . . .  
 And great anxiety is seen  
 In frequent family councils grave  
 As to what calling he shall have.  
 Law would cost father too much " tin."  
 As teacher he's not worth a pin ;  
 The aunt suggests theology.  
 " No ! that at least can never be ! "  
 Cries the whole family with misgiving ;  
 " In that he ne'er could get a living."  
 " No, dearest Auntie, in our day  
 Medicine is by a long way  
 The best—there is no doubt of it,  
 He could make something out of it."  
 Therefore, solely for the " tui,"  
 The fellow studies medicine.

Only that knowledge can be right  
 Which safely stands in black and white.  
 Therefore in notebook he records  
 The old professor's drowsy words,  
 And duly notes from A to Z  
 Whatever of practice he may see.  
 For observation is in minority  
 Against a pedagogue's authority.

Their therapeutical " arrangements,"  
 The way they classify " derangements,"  
 The methods they in treatment try  
 Are most convenient for a " b'y."  
 He does not need to doubt or quibble,  
 Only a daubed receipt to scribble ;  
 Goes only to his desk to seek 'em  
 From Doctor Docent's *Vade Mecum*  
 For every dullard's quick advisement  
 [It answers as an advertisement].

The examination makes him tremble.  
 Its terrors he can not dissemble.  
 He has no confidence in shamming,  
 So zealously resorts to cramming.  
 That which he has in lectures taken,  
 Trusting thereby to save his bacon,  
 He rolls forth without hesitation,  
 To each his wordy peroration.

At length he passes all the quæstors,  
 Is ranked among the " coming Nestors,"  
 Is titled *virum illustrum*  
 And all the rest of *quid* and *quem*,  
 Recorded in his grave diploma  
 In classic terms of ancient Roma.

Now Michael need not fear the future,  
 Although he know not pill from suture ;  
 Need not in science to speculate,  
 Nor theories to ventilate.  
 He has no use for such possessions  
 Now that he's joined the " learned professions."

Before his neighbors and relations,  
 Whatever their state or occupations,  
 The cousins, uncles, nephews, aunts,  
 Whether in petticoats or pants,  
 Wet-nurses, midwives, foul or neat,  
 The officers upon the beat—  
 He throws the dust in all their eyes,  
 That they his skill may advertise.

It's quite essential the first cure  
 Should be made pleasant, prompt, and sure.  
 One does well to select migraine,  
 For morphine will relieve the pain ;  
 Should this fail, as sometimes it will,  
 We've plenty of uareotic still ;  
 If thus we give the patient rest,  
 The laity is much impressed.

A syringe is his first selection  
 For subcutaneous injection.  
 Next to his heart it finds a place  
 Within a silver-plated ease.  
 Where " indications " he detects  
 He " symptomatically " injects.

Enough ; the valiant Michael quick  
 Is widely known among the sick.  
 But in regard to surgery  
 He shows a marked antipathy.  
 For pulling teeth he has a passion,  
 For knives are now quite out of fashion.  
 By salves much comfort is achieved ;  
 Fear of the knife is thus relieved ;  
 And should the patient not do well,  
 He's carted to the hospital.

Order 3. THE HONEST OLD FAMILY PHYSICIAN.

I turn my gaze from these delusive forms,  
 Bring from the shadows of the honored past,  
 Fond memory, the bravest of our race,  
 And let me glance at long-neglected worth.

No laurel decks thy brow, but where thy spirit true  
 Thy comrades showed the way to live and do,  
 There lives thy form, enthroned in every heart ;  
 There thou art still, and hast in life a part.

On the low couch within the chamber dim  
 A sufferer waits the last long struggle grim ;  
 Thou comest ; it is light, and sorrow disappears,  
 Pain is forgotten ; hope replaces fears.

So happy makes thy face, so brave thy kindly glance,  
The touch of thy loved hand brings ease and confidence.  
And, what with sordid gold can not compare,  
The tears of gratitude reward thy care.

I see thee, dearest councilor and best,  
The children's friend, the always welcome guest.  
Sorrow is shared, and doubled is the joy,  
Affection true, and trust without alloy.

I hear thy accents, fresh from noble mind,  
In language chaste, in motive always kind.  
Thy cutting satire, causing fools to quake,  
Who on some passing whim their fortunes stake.

Shall I entice thee to the motley crowd,  
Thou hoary guest of period long since past,  
That tricksters of an age beneath thy worth  
Should air their folly on thy classic robe?

Let us away from busy streets' commotion,  
Turning aside into the silent vale,  
And where some ancient comrade kindly beckons,  
There let us rest, and grant me thy communion.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. Walter Wyman, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for May 6th:

CITIES.	Week ending—	Population, U. S. Census of 1890.	DEATHS FROM—											
			Total deaths from all causes.	Pneumonia.	Yellow fever.	Smallpox.	Varicella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.

**Medical Misinformation.**—In an article with this title the *Druggists' Circular and Chemical Gazette* says: "The kind-hearted busy-body who is always ready to tell his sick friend exactly the right medicine to effect a sure cure is a bad enough person; but the newspaper prescriber is a great deal worse, for his utterances acquire a certain fictitious authority in the eyes of many people because they appear 'in the paper.' Some dangerous outbreaks of this kind of prescribing have lately occurred in several English journals. In one a 'cure for vertigo' was given in which 'glonoin' was directed as an ingredient. This article is much better known to the public by its chemical name, nitroglycerin, and the quantity of the 'cure' directed to be taken at one time would give the patient a two-grain-and-a-quarter dose of this violent remedy. In another paper a prescription for 'pains in the head' was given, in the taking of which the unfortunate patient would be dosed with a sixth of an ounce of nux vomica tincture

three times a day. Still another recipe in the same paper orders as a 'hair tonic' a seven-ounce mixture containing one ounce of strong ammonia water and two ounces of tincture of cantharides. The same style of medical tinkering may not infrequently be observed also in newspapers printed on this side of the water, although it is perhaps uncommon to find such dangerous ignorance displayed as has been recorded above. We have in mind a note on the treatment of insomnia, in which a mixture of chloral hydrate, potassium bromide, and codeine was directed in pretty stiff doses on the authority of a foreign physician, who 'highly recommended' it. The use of such a prescription under the direct supervision of a medical man and its employment by an unskilled layman might, of course, easily make the difference between life and death or between temporary help and the most wretched slavery. People have a great deal too much half-knowledge about drugs already, and the less attention they pay to newspaper prescribing the better. Here, as in the regular kind, the pharmacist is bound to stand between the patient and danger. When a customer comes to him with a nitroglycerin recipe or a blistering hair tonic he must promptly warn him of the true state of affairs, and by his watchfulness much damage can be averted and the cause of education be a little helped."

**To Contributors and Correspondents.**—The attention of all who purpose favoring us with communications is respectfully called to the following:

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Lectures and Addresses.

NEW OUTLOOKS IN THE  
PROPHYLAXIS AND TREATMENT OF  
TUBERCULOSIS.

THE MIDDLETON GOLDSMITH LECTURE FOR 1892,  
DELIVERED BEFORE THE NEW YORK PATHOLOGICAL SOCIETY,

By FRANCIS P. KINNICUTT, M.D.,  
PHYSICIAN TO ST. LUKE'S HOSPITAL AND THE PRESBYTERIAN HOSPITAL,  
NEW YORK.

GENTLEMEN: When your committee did me the honor to request my acceptance of the Middleton Goldsmith lectureship of the present year and suggested the subject—The Present Aspect of the Treatment of Tuberculous Disease, and especially of Pulmonary Tuberculosis—my first inclination was to decline. Their representations that a review of this subject was particularly desirable at the present time, and would serve a practical purpose, have alone induced me to undertake a difficult task.

The lecture has been postponed beyond the customary time of its delivery, in the hope that investigations which have been carried on during the past winter in St. Luke's Hospital and in the pathological laboratory of the College of Physicians and Surgeons might be sufficiently advanced to be incorporated in it. This hope, in part, has been fulfilled.

Any consideration of methods of treatment of infectious diseases at the present time must necessarily be in the light of modern pathology and bacteriology. Through the discoveries in this field of medicine the term *treatment* has acquired a new significance. A large number of the infectious diseases of human beings and of animals have already been shown to have their origin in specific pathogenic living organisms, and there are strong reasons for believing that a similar aetiology will be demonstrated in the near future for all diseases hitherto included in this category.

In the infancy of bacteriology it was not unnaturally assumed that the sowing of the seed was alone necessary for the production of a disease, that, if once the specific germ gained access to the economy, its particular effects would certainly follow. The "possession of a self-protecting power by the organism of man and of the higher animals, which could exercise its influence within certain limits either in arresting the development of the living exciters of disease or in counteracting their poisonous products," was hardly dreamed of. To-day the splendid discoveries of bacteriological research have abundantly demonstrated that an unceasing contest is being waged between the growing power and toxic activity of the pathogenic microphyte and the living organism.

In this connection, what can be of more absorbing interest than the discovery by the distinguished plant physiologist, Professor Pfeffer (1), of the group of phenomena to which he gave the name of chemotaxis, the definite relation between vital movement and chemical action? Later it was suggested by Dr. Leber that the emigration of leuco-

cytes in the human body was due to the same power; in other words, that certain harmful substances in the living tissues, embracing effete materials, living pathogenic organisms, and viruses of various kinds were agreeable to a rudimentary sense of taste, as it were, in the leucocytes, which were thus allured from the media in which they commonly lived toward the attracting substance.

The mustering of the leucocytes in troops, in the neighborhood of the bacterial invaders of the body, as a direct or indirect protection to it, is almost as dramatic as it is important. This action of the leucocytes, in virtue of their chemotaxis, and the final incorporation or digestion by them of the bacteria, constitutes Metschnikoff's well-known theory of phagocytosis and phagocytic immunity.

Further, we may refer to the investigations of Buchner (2) and Roemer, showing the association of a *general leucocytosis* with febrile inflammatory processes. They found that within eight hours after the intravenous injection in rabbits of various proteids there was marked leucocytosis; the relation of white to red blood-cells on the evening of the fourth day of the daily injection of solutions of the protein of the *Bacillus pyocyaneus* (the bacillus of green pus) was 1 to 38, the absolute number of the red blood-cells remaining unchanged. It should be mentioned that the office of policeman on the part of the leucocyte is not considered proved at the present time by many. Their work as scavengers is acknowledged, but it is believed that the true guardianship of the body resides in the body fluids; in other words, that the *destruction* of bacteria is accomplished by the germicidal power of the latter, and their *removal* only is effected by the leucocytes.

Finally, we may refer to the investigations which have shown that, while the living tissues and fluids of the body possess the power in varying degree of arresting the development of living disease-producing organisms and of eventually destroying them, certain life products of the latter are capable of impairing or inhibiting this protective power.

In view of such facts, preventive medicine must necessarily embrace the means of promoting the victory of the organism in its contest, either by strengthening its defenses or by weakening or destroying the power of the growing microphyte.

With our present knowledge of the various media in which the specific living exciters of disease most commonly lurk, it should be a matter of reproach if we fail in securing a more efficient prophylaxis than has been possible in the past.

Previous to 1882 the pulmonary lesions of tuberculosis had been accurately described, and Villemin, as a result of his successful inoculations of animals, had declared it to be a specific infectious disease. With the announcement of Koch, on March 14th of the year mentioned, that he had discovered not only the constant accompaniment but the cause of the tuberculous process, the infectious nature of tuberculosis was finally established and the nature of the relation between specificity of cause and specificity of process in this disease was determined.

Before proceeding further, it will be advantageous to have accurately pictured in our minds the pulmonary lesions which are directly or indirectly due to the tubercle bacillus. The list is indeed a formidable one: Miliary tubercles, both single and conglomerate; larger and smaller areas of epitheloid cell growth, called diffuse tuberculous tissue, and various aggregations of these, often in a state of more or less advanced coagulation necrosis; disintegration and excavation as a result of the latter; cicatricial formation; peribronchitis, and extensive inflammatory consolidations specific in nature; and, finally, we must bear in mind the bronchitis and lobular pneumonias, probably simple (unspecific) in character, so frequently present in tuberculous lungs.

In the light shed by modern research upon the possession by the organism of man of a self-protecting power against pathogenic organisms, with a knowledge of the specific organism which causes tuberculosis and the lesions which are directly or indirectly produced by its presence in the economy, we are proportionately equipped to attempt to consider the measures, prophylactic and remedial, which have been proposed to cope with the disease.

Prophylactic measures must necessarily consist of those designed to destroy the vitality of the bacillus outside of the human body, to minimize the sources of infection, and to render the tissues insusceptible to its presence.

Three possibilities suggest themselves as *specific* means for exercising a *remedial* effect. They are: First, the discovery of a method of treatment capable of destroying the bacillus within the body; second, of some substance, organic or inorganic, which by its introduction into the body may so modify the action of the bacillus as to deprive it of its harmful effects—the possible abstraction of a constituent of its protoplasm or of its metabolic products, analogous to the tetanus or pneumonic antitoxine, suggests itself in this connection; third, the discovery of a principle capable on introduction into the economy of increasing the germicidal power of the fluids of the body by stimulating cell activity, upon which it ultimately depends, or by such stimulation inducing connective-tissue changes in tuberculous tissue, or both.

PROPHYLAXIS.—I shall first consider the prophylaxis of tuberculosis so far as it relates to destroying the vitality of the bacillus outside of the human body, and to minimizing the sources of infection. With the discovery of the specifically infectious nature of a disease, the means of infection are not necessarily directly evident. In tuberculosis a series of brilliant investigations quickly threw much light upon this point. Following Koch's discovery, it was very early shown that the bacilli were not contained in the air expired by patients suffering from pulmonary tuberculosis; on the other hand, that their sputum contained bacilli in enormous numbers. It was further shown that the bacilli were incapable of escaping from fluid media, and, finally, that the sputum in a dry state, conveyed in the form of pulverized atoms by currents of air, was the most common source of infection. Successive investigations demonstrated that the stools of human beings afflicted with the intestinal form of the disease and the discharges from tuberculous

ulcers, glands, and bones were positive, if infrequent, vehicles of infection; and, finally, that the milk of tuberculous cows, with or without disease localized in the udder, and tuberculous meat, were capable of producing tuberculosis in the consumer.

It will be interesting to refer at somewhat greater length to inoculation experiments and clinical observations bearing on these points.

The elaborate investigations of Cornet (3) in the Berlin Institute of Hygiene in regard to the distribution of the tubercle bacillus in the air are particularly instructive. The dust from twenty-one wards of seven hospitals, from three asylums, from two prisons, from the living-rooms of sixty-two phthisical patients in private practice, from "out-patient" departments, from the public streets, and from inhalation experiment rooms, was gathered and its virulence or innocuousness determined by inoculation of susceptible animals.

Of ninety-four animals inoculated with the dust of hospital wards, twenty became tuberculous. Virulent bacilli were obtained from fifteen out of twenty-one medical wards. Negative results, on the other hand, were obtained from the dust of the surgical wards, also from that of the streets and the inhalation rooms investigated. Of one hundred and seventy animals inoculated with dust from the living-rooms of consumptives, thirty-four became infected. As ninety-one of the one hundred and seventy died of septic disease, it is probable that the above-mentioned percentage of animals in which tuberculosis was produced does not accurately represent the specific (tuberculous) virulence of such dust. The dust was taken from the walls, articles of furniture, picture frames, etc. From the room of a consumptive in a private house virulent bacilli were obtained six weeks after her death.

Cornet records the fact that he did not once find infective bacilli in the rooms of those patients who used only spittoons for the sputum, although especially careful search was made in these instances. Equally valuable evidence on this point is furnished by Trudeau (4). In his sanitarium at Saranac Lake, where rigid rules in regard to the use of proper receptacles for the sputum are enforced and its efficient disinfection or destruction is accomplished, not a single employee has acquired tuberculosis during the six years since its institution. In Dettweiler's sanitarium at Falkenstein, where presumably similar precautions are taken, a similar experience is alleged.

With such observations before us, further *clinical* statistics may be unnecessary, but are not without interest.

In response to questions sent in 1883 by the Collective Investigation Committee of the British Medical Association to physicians throughout Great Britain (5), asking for their personal experience on the communicability of phthisis, 1,078 communications were received. Of these, 673 were to the effect that cases of tuberculosis originating in infection had not come under their notice. Of the remaining 405, 261 were regarded by the committee as positive in evidence of communicability, 39 as doubtful, and 105 as negative. Among the affirmative observers, 192 reported cases of probable infection of husband by wife and the converse,

and in 130 of these cases there was an entire absence of inherited predisposition on the part of the person infected.

Turning to our own country, the investigations of Flick (6) are of much interest. The localization of and mortality from tuberculosis in one of the wards of the city of Philadelphia for a period of twenty-five years preceding 1888 were very carefully studied by him. It is shown that while less than one third of the houses of the ward became infected with tuberculosis during the twenty-five years prior to 1888, considerably more than one half of the deaths from this disease during the year 1888 occurred in infected houses. Inasmuch as there were more than twice as many non-infected as infected houses in the ward, a preponderance of deaths in non-infected houses would be expected.

Cornet's investigations of the health statistics of the Catholic nursing orders of Prussia (7) may be considered as supplementary to those of the same author which have already been described. Thirty-eight convents were selected, representing a yearly average of four thousand and twenty-eight persons, and the statistics relate to the twenty-five years preceding the year 1889. It is known that the general annual death-rate from tuberculous disease is from one seventh to one fifth of all deaths. Among the above-mentioned orders the enormous average mortality of 62.88 per cent. is shown to be due to tuberculosis alone. In nearly one half of the convents it even rises to seventy-five per cent., and in two "mother houses" it was the sole cause of death. In others the death-rate from this disease varies from forty to fifty per cent.

Cornet says that the different mortalities may be explained by the fact that some of the nurses are engaged in attending altogether or for the most part upon surgical cases. The average age at death of the inmates is 36.27 years, lower by ten years than that of men engaged in trades notoriously the most unhealthful—*i. e.* file-cutters, copper-smiths, locksmiths, blacksmiths, cotton-spinners, etc.

If the mortality due to tuberculosis and that resulting from other diseases commonly regarded as infectious are both deducted from the death-rate in the Prussian state and in the convents, it is shown that up to the age of forty years the death-rates in state and convents are remarkably equal. From forty to sixty years the mortality due to non-infectious diseases is less in convent than in state. Even admitting the insanitary conditions of convent life, it is impossible to believe, with our present knowledge of the ætiology of tuberculous disease, that it can produce it. On the other hand, these conditions are of the kind to lead to its rapid extension when once introduced. It should be mentioned that the health of all persons on entering the nursing communities is excellent, admission being dependent upon medical certificates to this effect.

Among the numerous investigations (8, 9, 10) of the infectiousness of the milk of tuberculous cows, I shall only refer to the very brilliant ones of our countryman, Dr. Ernst, of the Harvard Medical School (11). They surpass in their extent and importance those of continental observers. Experimental inoculations in rabbits and guinea-pigs, and feeding experiments in calves and pigs with both the milk and cream of tuberculous cows *without* disease of the udder,

proved in the most positive manner that such milk was capable of producing tuberculosis in the consumer. Incidentally, in experiments with milk taken at random from the common dairy supply of Boston, virulent bacilli were found in two instances.

If Dr. Ernst's experiments are supplemented with the clinical fact of the frequency of intestinal and mesenteric tuberculous disease in children and with the statement, made in the form of a resolution, by the United States Veterinary Association in 1889, that from ten to fifteen per cent. of the dairy stock of the Eastern States was tuberculous, this subject assumes very grave importance. Although investigations have shown that tuberculous meat as such is infective, further experiments are necessary to determine whether those parts of a tuberculous animal usually used for food, and not specifically affected, are harmful.

I have been able to collect a large number of cases of probable inoculation tuberculosis in the human being. Many of them occurred through infection of post-mortem and dissection wounds. Among others the following are of interest:

A healthy girl of fourteen years, without inherited predisposition, became locally infected through wearing the ear-rings of a consumptive. A tuberculous infiltration of the glands and general infection followed (12).

A male child, very vigorous at birth, began to suffer when three years old from eczema of the skin of the abdomen. Bacilli were searched for, but not discovered. After four years of age, he constantly slept with his consumptive mother, and bacilli were shown to be present in the eczematous vesicles (13).

A student received a slight wound in dissection; a nodule appeared at its site and a swelling of the glands of the forearm followed. The glands were excised and showed central cheesy degeneration (14).

Ten Jewish boys were circumcised by the same physician only a short time before his death from consumption. There is positive evidence that the saliva of the operator came in contact with the preputial wounds. The first symptoms of infection developed ten days later. Three of the children died of tuberculous meningitis, three of marasmus, and one of intercurrent diarrhœa. Three survived, but developed tuberculous adenitis (15).

Accumulated experimental and clinical investigations in demonstrating the most common sources of infection—*viz.*, the sputum of patients suffering from pulmonary tuberculosis, the milk of tuberculous cows, and finally, though to a much less extent probably, tuberculous meat—clearly indicate the direction which prophylactic measures should take.

The enormous number of tubercle bacilli contained in the sputum of patients suffering from pulmonary tuberculosis, even admitting that many of them are dead, as Kitasato very recently has shown, is well known. In a series of investigations kindly made for me by Dr. T. Mitchell Prudden in 1891, as many as 21,460,000 were computed to be present in the daily sputum of a single patient. Nuttall's experiments (16), conducted in the Johns Hopkins laboratory, give quite similar results.

Sawizky (17) has shown, moreover, that tuberculous sputum, dried and preserved under the conditions which usually obtain in the dwelling-house, preserves its infective properties for two months and a half.

Stone's experiments (18), if corroborated by further investigations, apparently show that its virulence may be extended for as long a period as three years. If we further consider the exceptional resistance of the tubercle bacillus to the action of both chemical and other antiseptics, the efficient disinfection or destruction of tuberculous sputum becomes a matter of vital importance.

*Chemical Disinfection.*—Carbolic acid, potassa, sulphate of copper, and chloride of zinc, all in solutions of 1 to 500, were found by Grancher and De Gennes to be useless (19). Histological examination of the sputum so treated showed no change in the appearance of the bacilli, and inoculations proved that they were still active. Later experiments (20) have demonstrated that carbolic acid, even in ten-per-cent. solutions and after twenty-four hours' admixture with the sputum, is without effect. Corrosive sublimate is valueless through the coagulation produced by it of the albuminoids contained in the sputum. The experimental investigations of Schottelius and Spengler (20) with the newer antiseptics—creolin, aseptol, and lisol—of which much was hoped, have also been disappointing. Ten-per-cent. solutions of creolin and aseptol were found to be absolutely without effect, even after twenty-four hours. Lisol, however, in ten-per-cent. solutions, proved to be capable of rendering the sputum sterile in twelve hours.

These results indicate in the most positive manner that we possess no practical means at present for efficiently disinfecting sputum by chemical antiseptics.

Experiments with heat, on the other hand, have shown that the tubercle bacilli rarely survive a temperature of 80° C., and are invariably killed at temperatures varying, according to different observers, from 90° to 100° C. (21). Simple rinsing of the cups or other receptacles of the sputum with boiling water is not sufficient and is not without danger to the attendant. Numerous observers report cases of infection of cuts from sputum (*v.* Eiselberg [22], Fleur [23], Holst [24], L. Pfeiffer [25], and others).

In view of these facts, every consumptive should possess the knowledge that, while his disease is in reality a menace to those about him, the foil is within his reach. He should be taught never to use a handkerchief for his sputum, never to spit upon the floor. An appropriate receptacle of glass, china, or paper, partially filled with water, should be provided for the sputum, which should be thoroughly disinfected or destroyed at least once in twenty-four hours. For its disinfection in hospitals, an ordinary Arnold's sterilizer, of sufficient size to accommodate all the cups of a ward, and in which they should be placed daily for half an hour, may be used.

A far better method, in my judgment, is the destruction of the sputum by fire. The method at present in successful use in St. Luke's Hospital, and which is of easy application in private houses, consists in the use of paper boxes, which are daily supplied to each patient, and at the end of twenty-four hours destroyed, with their contents, by fire. They are of convenient size and very inexpensive, and the preparation used in their construction prevents all leakage. The floors and the walls of living-rooms and of hospital wards of consumptives should be scrubbed or wiped with

damp cloths, not swept or dusted. The cast-off clothing of such patients should be submitted to the action of live steam, or to the degree of heat described as sufficient to destroy the tubercle bacilli.

Public sentiment, in the absence of legislation, should compel the proprietors of hotels and boarding-houses at health resorts, at least, to take such measures as can be designated with our present knowledge for disinfecting the living-rooms of consumptives. Further investigations are urgently needed to determine the most efficient and practical means for accomplishing this object.

A further most important prophylactic measure consists in the systematic inspection of dairies, particularly those of large cities, and of slaughter-houses. Commercial considerations have secured the necessary legislation for the inspection of the pork products of the United States; a consideration of the public health should be sufficient to secure a similar legislation to minimize the sources of infection of tuberculous disease.

A bill for the inspection of dairies and the slaughter of tuberculous animals, I am happy to state, will probably be introduced in the Legislative Houses of the State of New York during the present session. Such an example, it is reasonable to hope, would gradually be followed by the Legislatures of other States.

In the mean time, in the absence of necessary legislation, the only safeguard possessed by the public against possible infection through dairy products consists in the sterilization of milk and cream by boiling or through the use of steam sterilizers.\*

Many of the prophylactic measures which have been mentioned have already been embodied in the form of suggestions or in laws by various governments and municipalities abroad, and the Board of Health of the City of New York has issued some admirable rules "to be observed for the prevention of the spread of consumption."

In considering the prophylaxis of tuberculosis I have confined myself to measures designed to destroy the vitality of the bacillus outside the human body and to means for minimizing the sources of infection, in the belief that such efforts are of far greater relative value than those directed toward increasing the resisting power of the individual. I shall even go further, and thus cease to be open to the reproach that the clinician's interest in the therapeutics of the disease is almost to the exclusion of that in its prophylaxis, and assert that infinitely more can be accomplished toward the elimination of this terrible scourge by making practical use of our present exact knowledge of its aetiology and prophylaxis than by any or all therapeutic measures at present at our command. As has been well said, "it is the seed of the disease, without the implantation of which there can be no harvest of death, that we are now most able to reach and destroy." We shall fail, then, in our duties as true physicians if we do not scatter broadcast among the laity this knowledge. From a full appreciation of the dangers at their doors and a knowledge of the means capable of divert-

\* Investigations conducted in the Imperial Health Bureau of Berlin demonstrated that tubercle bacilli also retain their vitality in butter and cheese frequently for weeks.

ing them, surely good fruit will be borne, even to the enactment and enforcement of laws for the protection of the public health.

In turning our attention to the remedial treatment of tuberculosis our thoughts naturally are first directed to Koch's tuberculin (26). His hypothesis of its specific mode of action is as follows: He particularly states that other explanations are possible and may be more correct. The tubercle bacilli in their growth produce in the living tissues, just as in artificial cultivations, certain substances which have various but always deleterious effects upon the living elements of their surroundings, the cells. Among these substances is one which, in a certain concentration, destroys living protoplasm and causes it to undergo what is known as a coagulation necrosis. The necrotic tissue is unfavorable to the nutrition of the bacillus; its further development is checked, and finally, in some cases, its death follows. If the amount of the necrosis-producing substance is artificially augmented, as he believes it to be by the introduction of tuberculin into the system, not only will the extent of the necrosis be increased and consequently the conditions of the nutrition of the bacilli be more unfavorably affected, but also more completely necrosed tissues will disintegrate and slough, and, where this is possible, take with them the inclosed bacilli, carrying them outward. Large doses of tuberculin are capable of giving rise to a certain amount of pyrexia and other symptoms in healthy persons, he believes through irritative influences exerted upon certain elements of the tissues, probably on the white corpuscles of the blood or cells closely related to them. The necrosis-producing substance in tuberculin Koch now tentatively believes to be an albumose or a substance closely related to it.

Many elaborate criticisms of this hypothesis, both theoretical and based upon experimental and clinical investigations, have appeared during the past year.

In a very recent monograph by Rosenbach (27) the author denies both a specific affinity of tuberculin for tuberculous tissue and the specific action alleged for it. The general action and constitutional disturbance following its inoculation he believes to be due to a general irritation set up in the body, which, according to its degree, can assume the characteristics of an inflammatory action, in some cases even of a purulent type. The degree of the reaction, particularly of the fever, depends upon the predisposition of the individual to febrile disturbance. Similar constitutional disturbances have been shown to follow the inoculation of cantharidal salts and the protein of other bacteria. Rosenbach asserts that the specific activity of tuberculin can only be demonstrated when it is proved that substances derived from other micro-organisms can produce fever exclusively in subjects who are the hosts of bacteria of the same kind, and, further, that they can evoke reactions only in the tissues in which changes have occurred from their action and elsewhere remain without effect. He maintains that hitherto this has not been shown. The author expresses a guarded opinion as to whether tuberculin produces an actual necrosis of tuberculous tissue; if it occurs, he believes it is not a coagulation (specific) necrosis, but

rather is secondary to an acute inflammatory process and exudation.

A new light has been thrown on the nature and action of tuberculin through the investigations of William Hunter, of England, and the German pathologist Klebs. As early as January, 1891, the former began his investigations (28). Starting with the assertion of Koch's that the remarkable properties possessed by it—unfortunately for evil as well as for good—were due to a single active principle which constituted but a fractional part of the extract, he believed that the chemical behavior of this hypothetical principle, which was described by the discoverer as a derivative of albuminoid bodies, could not possibly apply to any one known chemical substance.

His studies had for their objects:

(1) To isolate the chief constituents of tuberculin and to determine their chemical nature; (2) to ascertain their action, with special reference to their power of inducing the two most characteristic effects of tuberculin—viz., local inflammation and fever; (3) to ascertain how far it was possible to eliminate all substances having an injurious action, and thus to obtain remedial without injurious effects.

His results may be summarized as follows, under the heads of composition, action, and therapeutic value:

The chief substances found in tuberculin are: (1) albumoses;\* (2) alkaloidal substances; (3) extractives, small in quantity and of unrecognized nature; (4) mucin; (5) inorganic salts; (6) glycerin and coloring matter.

Having ascertained that the only substances present in tuberculin with which its active properties could be associated were albumoses, organic bases of alkaloidal nature, and probably various extractives, he proceeded to determine by experiments on mice and guinea-pigs to which of these substances tuberculin owed its characteristic properties, remedial or other.

Four modifications of the original tuberculin were accordingly prepared by him. He has given to them the designations *A*, *C*, *B*, and *CB*, and these terms will be retained in the present paper.

From extensive investigations with these modifications, he feels warranted in concluding—

1. That tuberculin owes its activity, not to one principle, but to several; that its action in producing local inflammation, fever, and general constitutional disturbance is not a simple but an extremely complex one.

2. That its remedial and inflammatory actions are connected with the presence of certain of its albumoses, while its fever-producing properties are chiefly associated with substances of a non-albuminous nature.

3. That by the adoption of certain chemical methods it is possible to remove the substances which cause the fever, while retaining those which are beneficial in their action.

4. That the fever produced by tuberculin is thus absolutely unessential to its remedial action. (He is inclined to believe that the inflammation is almost similarly unessential, although admitting that under certain circumstances it may assist the action of the remedial substance.)

\* Chiefly proto-albumose and deuterio-albumose, along with hetero-albumose and occasionally a trace of dysalbumose.

5. That tuberculin possesses a truly remedial action and that this is to be found in a protein—*i. e.*, in an albuminous substance derived from the plasma of the bacilli themselves and not formed by their action upon the surrounding tissues; and, finally, that it is possible to isolate largely this protein.

Dr. Hunter's clinical investigations, in which he has been assisted by Mr. Watson Cheyne, with the above-described modifications of tuberculin, have led him to assert tentatively the following propositions: Modification *A* differs but slightly in its action from tuberculin. Modification *C* differs from tuberculin in being almost completely freed from the substance which gives rise to local inflammation. It contains, however, in a special degree the fever-producing agents, which may be regarded as interfering with its remedial properties and favoring rather than retarding the growth of the bacilli. Modification *CB* contains the remedial substance present in *C*, freed from the fever-producing agents. Its use, moreover, is unattended with any of the other constitutional symptoms following the employment of tuberculin. Modification *B* contains the remedial properties of *CB* with the additional property of inducing local inflammation. Its action is free, so far as has yet been observed, from ill effects.

From the marked improvement which Dr. Hunter has seen occur in cases of ulcerative and other forms of lupus, where it is possible to watch the local changes from day to day, under treatment both with *B* and with *CB*, he believes the activity and probable remedial power of these modifications to be demonstrated. It yet remains to be determined whether the improvement noted in his cases will be more or less permanent. The absence of marked local inflammation, or of necrotic changes accompanying their use, leaves the mode of action of the above-mentioned modifications of tuberculin a matter of more or less speculation at the present time. I shall refer later to the clinical investigations of other observers, and to some personal ones with Dr. Hunter's preparations.

Professor Klebs's researches evidently have been based on the same line of thought as the foregoing, but were made quite independently of them (29). Convinced that tuberculin produced in the human being many effects which had nothing to do with its action upon tuberculous tissue, and which could be avoided without affecting the latter property, he submitted tuberculin to various chemical processes with the view of freeing it from its alkaloidal substances. Its noxious properties reside in the latter, he believes.

He maintains that the extracted principle represents the secretions of the tubercle bacilli and is a pure albumose. Experimental investigations in animals indicate that the injection of large doses of *tuberculoëidin*, as he terms the albumose, previous to inoculation with pure cultures of the bacillus, delays the development of tuberculosis to at least twice the usual period; moreover, that a complete resolution of previously developed tubercle may occur under its use.

The best results in animals were obtained when the tuberculoëidin was injected simultaneously with inoculations of the bacilli. In such animals, killed three months

later, tubercle was scantily present, and few bacilli were found. In cases where treatment was begun six weeks after experimental inoculation and continued for twenty-five days, either complete healing or a high degree of retrogradation of the tuberculous lesions was observed.

Of seventy-five critically observed cases of pulmonary tuberculosis in the human being treated with tuberculoëidin, 18.6 per cent. are alleged to have been cured, and sixty per cent. improved. In a single case of supposed tuberculous meningitis the symptoms also improved. Cases are reported in detail by Klebs in which a successful issue occurred, both tuberculin and creasote having previously failed to give good results.

The treatment being practically unattended with constitutional disturbances or fever, there is no interference with the customary life and occupation of the patient.

As far as I am able to judge from Klebs's statements, the remedial properties of tuberculoëidin reside wholly in its germicidal power—*i. e.*, in its ability to destroy the tubercle bacillus within the human body. He expressly states that no inflammatory process or necrosis of tissue is produced by it.

If Klebs's very positive statements on these points are borne out by further, extended observations, a far-reaching and very brilliant discovery has been given to the world.

In concluding his report, Klebs remarks that it only remains to determine the limitations which control the cure of the disease produced by the specific bacillus whose destruction we have succeeded in accomplishing. The first cause may vanish, and yet the pernicious results of the conditions developed from it remain. When advanced destruction of pulmonary tissue has occurred, where the general vitality has greatly depreciated, and emaciation and marked impairment of the heart's function have taken place, cure is no longer to be expected, even with the removal of the first cause of these conditions.

We have now to consider some very interesting and noteworthy investigations of Roemer and Büchner (30).

The former, as the result of his experimental researches, has made the surprising announcement that the same reactions can be obtained in tuberculous guinea-pigs from inoculations with protein-containing extracts from the *Bacillus pyocyaneus* (the bacillus of green pus) as with tuberculin. He found that tuberculous animals died quickly after injections of such extracts, while healthy animals lived; that lesions occurred in the liver and spleen of such animals apparently quite similar, both macroscopically and microscopically, to those described by Koch as due to the specific action of tuberculin. Büchner has corroborated Roemer's observations of the effect of injections of the protein of the *Bacillus pyocyaneus*, and has found similar effects to follow the use of the protein of other bacilli—*viz.*, *Pneumobacillus (Friedländer)* and the *Bacillus prodigiosus*. Inoculations of healthy men with minute doses of the protein of the *Pneumobacillus* or the *Bacillus prodigiosus* were followed by redness and swelling at the point of injection and a local rise of temperature, which gradually disappeared and were of quite similar character in the different persons experimented upon.

Constitutional symptoms were not produced, Büchner suggests, on account of the smallness of the dose administered. The pronounced local reaction, in comparison with that of tuberculin, he believes to indicate a more serious action of the protein. Büchner concludes his report on his investigations as follows: "Are the protein extractives of the tubercle bacillus alone capable of exciting a latent irritation to an appreciable inflammation and necrosis?" "Are not other ordinary exciters of inflammation, especially proteins from harmless kinds of bacteria, possessed of the same power?" The observations reported by him, he thinks, speak favorably for such a possibility and open, therefore, in a practical manner, new and perhaps not unimportant outlooks.

In the light of extended experimental investigations and of very numerous clinical observations, the incorrectness of many of Koch's original hypotheses and conclusions is evident. It has been shown that tuberculin contains not one but several active principles, respectively capable of producing different effects; that whatever remedial action it may possess resides *apparently* in certain of its albumoses, while its harmful properties are seemingly due to the non-albuminoid substances present in the extract. With the knowledge that tuberculin is the concentrated fluid medium in which the bacilli have been growing, thus presumably containing both the products of their growth and the proteins derived from their bodies, Prudden's experimental studies (31) of the action of *dead tubercle bacilli* would seem to be further corroborative of these views. His experiments indicate that the dead bacilli, freed as far as is possible from the products of their growth, are capable of enormously stimulating cell activity and of producing lesions morphologically similar to tubercle, but which are not *indefinitely progressive* and *do not tend to the production of an advancing coagulation necrosis*, and, finally, *do not induce an infectious disease*.

A legitimate conclusion from these observations would seem to be that the coagulation necrosis which Koch's hypothesis regards as the remedial mode of action of tuberculin is dependent upon a metabolic product of the growth of the bacillus.

In view of the remedial effects obtained by Hunter, Cheyne, and Klebs from the use of a tuberculin presumably freed from metabolic products, and the apparent demonstration by Prudden that a constituent of the *protoplasm* of the dead bacillus, probably a protein, is capable of enormously stimulating cell activity, it is justifiable to feel that much light has been thrown upon a most complex question.

Whatever beneficial results were obtained from Koch's original tuberculin, I am convinced were not through, but in spite of, a production of coagulation necrosis; and that the benefit alleged to-day by many from its use in exceedingly small doses is partly through the avoidance of such an effect. In exceedingly minute doses it is possible that the action of the cell-stimulating protein preponderates, and thereby a remedial influence is exerted.

A rather large clinical experience, now extending over a period of eighteen months, leads me to reiterate an opinion previously expressed that "*tuberculin contains a remedial principle*." This view is shared, among our own country-

men, by Trudeau and von Ruck, gentlemen who have enjoyed in their sanatoria the widest possible opportunities for thoroughly studying the subject.

In a recent communication by Schede, of Hamburg (32), than whom no continental surgeon has a larger clinical experience, a similar opinion is expressed. In concluding this portion of my subject I can not but express my abiding and earnest belief that the continued and exhaustive investigation of Koch's discovery will lead either to such modifications of the original extract, or to the preparation of a new one based upon a similar principle, as will place in our hands an agent specific in character and remedial in tuberculosis in a degree hitherto believed to be unattainable.

The results obtained in the wards of St. Luke's Hospital in the treatment of pulmonary tuberculosis with modifications of tuberculin already effected will be appended to the present lecture.

THE TREATMENT OF PULMONARY AND LARYNGEAL TUBERCULOSIS BY THE CANTHARIDATES.—In February, 1891. Professor Liebreich, in a paper read before the Berlin Medical Society, announced that he had discovered a new remedy for the treatment of tuberculous disease. The property of cantharidin, when taken internally, of producing an exudation of serum from the capillaries, not only of the kidneys, but also of the lungs and other organs, unattended with increased arterial tension, hyperæmia, or extravasation of blood, when used in sufficiently small doses, forms the basis of his theory. The irritability of the capillaries, according to Liebreich, varies in different parts of the organism in health; in an abnormal state, such as may be assumed to be their condition at the site of local disease, this irritability is increased. By furthering such irritability by the use of the cantharidates, an exudation of serum occurs which may favorably affect tuberculous tissue in two ways: (1) by stimulating cell activity and nutrition, (2) through the germicidal action of the serum upon the bacteria. His experimental investigations apparently indicate in a measure the correctness of his theory.

The remedial effects which have followed the use of the cantharidal preparations, while occasionally striking, especially in the case of laryngeal tuberculosis, fall short of securing for them, it seems to me, a permanent place in the therapeutics of tuberculosis. Their apparent action is in harmony with one of the possible means of a remedial treatment of tuberculosis. Cell activity is stimulated, and specifically diseased tissues are subjected to the germicidal action of the blood serum, artificially increased at the site of disease. There is a failure possibly in the degree rather than in the kind of action. The preparations at present employed are the potassium and sodium cantharidates. They are administered hypodermically at intervals of forty-eight hours or longer, and in doses of  $\frac{1}{640}$  to  $\frac{1}{320}$  grain. The latter strength not infrequently causes symptoms of vesical and renal distress.

Their use is contra-indicated in the presence of intestinal and renal disease, and in patients with marked hectic.

TREATMENT WITH THE SERUM OF DOG'S BLOOD.—The interesting experimental investigations of Richet and Héricourt, announced during the past year to the French Acad-

emy of Sciences (33), with the serum of dog's blood in the treatment of tuberculosis are in the line of thought that at present underlies our attempts to cope with the disease. These observers have been able to demonstrate that in rabbits inoculated with a culture of the tubercle bacillus the evolution of tuberculosis can be arrested by subsequently subjecting the animal to injections of dog's serum. When very virulent cultures are employed, the evolution is only delayed. Injections of a healthy animal with the serum prevent the development of experimental tuberculosis at a later period.

The effective substance has not been identified as yet, but a small dose of the serum is sufficient (0.5 c. c. to the kilogramme of the rabbit).

The clinical results obtained in tuberculous disease of human beings by this method of treatment, which has been fully tried in the Paris hospitals, would indicate that it also fails rather in the degree than in the kind of its action. It certainly acts as a potent stimulant to cell activity. Whether it possesses another action is undetermined.

**THE CHLORIDE-OF-ZINC TREATMENT.**—I shall briefly refer to the treatment of tuberculous disease with chloride-of-zinc injections at the site of the disease, announced to the French Academy of Sciences in July of the past year by Professor Lannelongue (34).
